A much more conventional approach is taken by Gareth Renowden and Nigel Hawkes in **Video** and **Space Shuttle**, respectively (Collins/Gloucester Press; £2.95, $9.40), in the *Inside Story* series. Each has 30 large pages, with illustrations taking more space than text. There are diagrams, cut-aways, a little technical data, a glossary and an index but in the end too much knowledge is assumed and too little information provided. Nevertheless these are attractive books of some value.

For something completely different your child might like to learn that 'flu viruses from outer space can result in the spread of epidemics on Earth. It's Fred Hoyle again but here in combination with his son Geoffrey and with the decency for the sake of children to wrap his proposals firmly in the cloth of science fiction. **The Planet of Death** is one of four of their science fiction books, published by Ladybird at 60 pence ($1.95) apiece, and all good yarns. *The Planet of Death* is typical: William, a good schoolboy, has considerably less time for the vivacious Kiryl than for her father, Professor Gamma, who is adept at the art of dematerialization when it is necessary for our three heroes to visit another planet.

11-year-olds and over

There are both books of facts and books of experiments for this age group, the former including three *Granada Guides* on **Fossils, Computers** and **Robots** (£1.95 each). Pocket-sized, with glossary, index and many illustrations, children will find them nice enough to dip into but not especially good as serious reference books. More on computers is to be found in the 40 double-page, large-format **Discovering Computers** which, with **Discovering the Weather,** is the latest in Longman's *Discovering* series (£6.95 each; Little, Brown, $12.95 each). The writing is dull and the approach dry but the child already interested in either subject would be happy to be given them.

Far less routine and largely successful in their intent are numbers 9 to 12 in the series *How We Found Out About . . .* by Isaac Asimov, also from Longman (£2.75 each). Published in the 1970s in America by Walker, these four new volumes deal with **Energy, Germs, Antarctica** and **Dinosaurs** (what, no computers?), largely from a historical point of view. *Germs,* for example, starts with the first microscope and ends with the discovery of viruses. The usual childish angles are largely eschewed — there is almost nothing on the death of dinosaurs or solar energy — but a whole chapter on entropy. Not surprisingly, Asimov carries it off with ease.

Thorough assessment of the five books of experiments would have taken more time and children than were available. In the case of **How to Make Square Eggs** by Paul Temple and Ralph Levinson (Beaver, £0.95), the title experiment worked but I cannot guarantee equal success for the square tomato (start with a seed and encase an infant fruit in a box) or for the experiment entitled "A plant that eats animals" (first buy a Venus fly trap). A paperback, with 40 experiments rated by difficulty and some aimed for the classroom rather than home, it would engender both amusement and frustration. Leonard Marsh's **The Guinness Book for Young Scientists** (GBR Educational, £2.95) is better in that most of the experiments use household materials, although very basic chemistry apparatus is required for some and a trip to the chemist for others. Experiments include how to make plastic from milk and hydrogen sulphide from a metal bottle cap!

Like the other books from Methuen-Walker, **Amazing Air** and **Supermotion** (£3.95 each), two of the *Science Club* series, are beautifully designed and illustrated. There are about 30 experiments in each book, carefully explained and illustrated, step by step, with attention to detail, supplies and safety. *Amazing Air* has experiments on such phenomena as air pressure, oxidation and electrolysis; spinning, magnetism and balance are included in *Supermotion*. Morrow will publish the books in the United States in spring 1983, price $5.25.

Last, but very definitely not least, is **The Science Book** by Sara Stein, a book first published in the United States and now available in Britain (Heinemann/Workman; £4.95, $6.95). It is full of humour, zany facts (why don't cats beg for cookies? — because they have no taste receptors for sugar), and experiments to attract and educate children. To learn about kidney function, eat asparagus and follow your nose. Get to grips with the genome by cloning a plant (unfortunately for British readers, here the recommended species are all American) and with anatomy by checking out the chicken bones on a Sunday roast.

The Science Book is not simply a list of experiments. Rather it is an unorthodox primer, with unorthodox demonstrations, on much that is of interest to a growing child. There are sections on charges (electrical and magnetic), protists and plants. But the bulk of the book is concerned with physiology while chemistry and genetics get a reasonable look in. This is the only book of the whole batch to be centred on such sciences; for that and its refreshing approach, I give thanks and can forgive some errors of judgement. □

Peter Newmark, the father of a six-, a nine- and a twelve-year-old, is Deputy Editor of Nature.

Risibility research reviewed

William H. Press

More Random Walks in Science. Compiled by Robert L. Weber. Pp.207. ISBN 0-85498-040-7. (The Institute of Physics/Heyden: 1982.) £9.95, $19.50.

WE TRY to keep it a secret, but we all know that research and teaching are not what science is all about. Rather those doubtless worthy activities are pale diversions from the real business of science, namely the invention, dissemination and elaboration of funny anecdotes about colleagues, parodies, doggerel and the occasional pithy aphorism or *bon mot.*

A Random Walk in Science, which was published about a decade ago as a collection of such fundamental material, has come to be held as a kind of *urtext* for all science, the ultimate peak of that pyramid which begins with primary publications at the bottom and then ascends to review articles, reviews of reviews and so on.

Now this sequel, collecting some 175 or so additional short pieces, can be added to that lofty edifice. Here, for everyone, there is something, whether whimsy like "The Use of Small Dogs in Physics Teaching" or broad jokes like the investigator who ate dehydrated food for 28 days and then gained 108 lbs in ten minutes while caught in a rainstorm. Parody ranges from the predictably amusing "I am the very model of . . .", to the arcane, such as Shelley's *Ozymandias* ("Two vast and trunkless legs of stone/Stand in the desert . . . Look on my works, ye Mighty, and despair!. . .") rewritten as the geology paper "Twin Limb-like Basalt Columns and Their Relationship to Plate Tectonics".

Scientists cannot resist applying scientific observation to their own endeavours, yielding, for example, a description of their university hierarchy, from the Dean who leaps tall buildings in a single bound, through Professor (leaps short buildings with a running start and favourable winds), graduate student (runs into buildings) and finally department secretary (lifts buildings and walks under them). There is also a piece which rings true on the various types of obstructionists on committees and panels, and another on the "game" of refereeing. (The author's goal is to publish a worthless paper; the referee's is to have a major contribution to the field refused. "No matter what degree of rigor the author uses, the referee replies by saying that it is not the correct one.").

Anecdotes are nicely represented. We have the famous theoretician Sir Harold Jeffreys, consultant to an oil company, listening attentively to a full day's presentation and then offering his (only) advice: "I'm glad it's your problem and not mine". We have Bessel receiving from King Friedrich Wilhelm not the needed funds to improve his observatory, but rather a medal for having attained such excellent results with primitive equipment. We have Pauli in heaven, hearing with mounting impatience God's explanation of the proton–electron mass ratio and finally snapping back, "Wrong!". And Rutherford's memorable encounter in a glass-teapot works.

Literary hoax is represented by the paper coauthored by a cat (so that the sole human author could use the word "we" over an editor's objections), and by the biography of Claude Litre, the celebrated eighteenth-century maker of wine bottles after whom the volumetric unit is (putatively) named.

Courtesy Cambridge Medical Instruments Ltd.

From *More Random Walks in Science*.

Having fun in the laboratory? This doleful character appears to have doubts about the safety of the original electrocardiograph (*c.* 1911).

The volume also contains perhaps the finest scientific biography of Sir William Rowan Hamilton ever penned, here quoted in its entirety:

Higgledy, piggledy
William R. Hamilton
Wrote on mechanics, in-
Frequently joked,

Wrote on quaternions,
Tackled intractable
Hydrodynamical
Problems, and croaked.

While perhaps unsuitable as an introductory text, this volume will certainly fill the needs of advanced students and practitioners in the field. □

How to be a scientist

Walter Gratzer

Winning the Games Scientists Play. By Carl J. Sindermann. Pp.285. ISBN 0-306-41075-3. (Plenum: 1982.) $15.95, £10.05.

WE ALL agree that there is more to science than doing research. The politics of professions in which scope for the exercise of power is limited or illusory, such as the academic or the ecclesiastical, tend to be conducted with particular ferocity and vindictiveness, redeemed only by the incompetence of most of the protagonists. It is a subject that invites satirical dissection: someone should do for our profession what A.P. Herbert did for (or to) the law.

I picked up Dr Sindermann's book with eager anticipation. The title is full of promise and from the dust-jacket the author, wearing a natty check and the suggestion of a knowing smile, looks at one appraisingly with gimlet eyes — clearly A Man that Waiters Spring to Serve. I averted my gaze and turned to page 1. But what was this? The first sentence averred that the book had been written for "thousands of serious dedicated scientists", such as myself, "to ensure that they [may] participate fully and joyously in a genuinely wonderful occupation". If this was a manual of gamesmanship for the scientist it evidently owed little to Stephen Potter and all too much, if not to Lord Chesterfield then certainly to Dale Carnegie: how to win patrons and influence the Federation of American Biochemists.

There is, it is true, a sprinkling of anecdotes and many a genial aside, but there is not much levity, for Dr Sindermann's purpose is serious. His thesis is that for most scientists, the pleasures of the laboratory bench are in the long, or even the short run inadequate; and that if they are to enjoy a full and rewarding career they have no option but to throw themselves into the parascientific activities that beckon on all sides, such as attending and preferably organizing meetings, sitting on committees and running international commissions. He would evidently reject the proposition (first enunciated, I believe, by no less an authority than Professor Milton Friedman) that useless work drives out useful work. In short, while insisting that there is no substitute for prowess at research, Dr Sindermann urges his readers to join that travelling circus of Flying Dutchmen, whose chief and urgent preoccupation it is to keep as far away from their laboratories for as much of the year as possible, and leave the research in the calloused hands of their postdocs, technicians and PhD students.

As a guide to social and professional advancement in such company, the book is, so far as I can judge, excellent. Its most insistent message is that one must cultivate an uncompromisingly professional approach to all the activities in question — including even the successful pursuit of your quarry at the conference cocktail party. Dr Sindermann dispenses much good advice on how to give a paper at a meeting, how to make effective use of slides and how to deal with discussion. He descants on the best way to run a session and on the problems of organizing the whole affair yourself. Anxious novices will no longer have to discover the hard way where to go for financial sponsorship, how to cope with recalcitrant and temperamental foreigners and what to watch out for in drawing up an agreement with a commercial conference organizing company. Dr Sindermann writes here with an authority that can only stem from long experience and careful study.

On the more general aspects of the *arriviste's* upward trajectory, however, such as the craft of committee chairmanship (or in the Newspeak favoured by Dr Sindermann, chairpersonship), he has much less to say that is not a mite obvious. He does not offer such helpful hints in Advanced Chairmanship Technique as that once imparted to me by an expert in the field: ensure that the room is overheated and make large volumes of tea and coffee available, so that the ensuing discomfort will inhibit prolonged argument when eventually you introduce the issue of real importance. Again, it is related that Maurice Bowra, a university politician of transcendent virtuosity, would overturn a ten to one majority against him by observing that an *impasse* seemed to have been reached, and perhaps therefore the meeting should be adjourned. Dr Sindermann's advice in his "chairman's creed" is more along the lines that a chairman must be firm but not domineering. Most of what he has to say might be more succinctly summed up in Senator Dirksen's well-known adage that the oil can is mightier than the sword.

In the later chapters there is a good deal of padding, and to my mind not much that is helpful when it comes to coping with the "midlife crisis" or with such alien forces as probing politicians from the outside world and women in the laboratory. It is curious that a book which encompasses such a wide range of opportunities and pitfalls — and even advises you how to deport yourself in the laboratory when in the throes of lust — makes not a mention of teaching. We are meant to conclude presumably that this is an occupation that plays no part in the process of getting ahead.

Dr Sindermann is an Establishment man. His advice is that you order your life according to Establishment rules, and then you too may become known for being noted. He has no patience with the unsuccessful and mediocre, who, he holds, are simply not trying: you should show them no mercy. His book may well help to reclaim some of these fallen, and should give encouragement to the walking wounded in the battle for academic survival. But where it may comfort the afflicted, it will certainly not afflict the comfortable. There are, it seems to me, more useful maxims for young scientists, struggling to prevail in a hostile climate, than any that Dr Sindermann has to offer. One that seems to me to encapsulate an enduring truth comes from Alexander Cohen's *Journal of Irreproducible Results* and goes like this: if a research project is not worth doing at all, it is not worth doing properly. Cap that, Dr Sindermann. ☐

Walter Gratzer is in the MRC Cell Biophysics Unit, King's College, University of London.

Now you solve it, now you don't . . .

Aha! Gotcha: Paradoxes to Puzzle and Delight. By Martin Gardner. Pp.164. Hbk ISBN 0-7167-1414-0; pbk ISBN 0-7167-1361-0. (W.H. Freeman: 1982.) Hbk $15.95, £11.20; pbk $8.95, £5.60.

MARTIN Gardner is probably best known for his feature in *Scientific American*, "Mathematical Games", which ran regularly from 1956 to 1981; but he has also published many other articles and books, both light-hearted and serious, on mathematical topics. *Aha! Gotcha* is definitely light-hearted, but still true to its subject, and similar in format and spirit to its companion-volume *Aha! Insight.*

Both books contain about 70 self-contained entries, each exploring some intriguing mathematical trick, puzzle or theorem. *Aha! Gotcha* deals with paradoxes, pointing out the role they play in sharpening mathematical reasoning, and presenting them in six sub-divisions: logic, number, geometry, probability, statistics and time (this last strays over the boundary of mathematics into physics).

Here are discussed the familiar paradoxes of self-referring statements (the lying Cretan), infinite sums and curves (the Snowflake), probabilistic fallacies (Pascal's wager) and the Zeno paradoxes (Achilles and the tortoise). Here also are many more modern and subtle paradoxes: the Unexpected Tiger, Newcomb's paradox of the perfect thought-reader, the voting paradoxes which subvert our hopes for a perfect democracy.

Each entry provides a simple but well-reasoned discussion of the chosen paradox, and some examples — one of them in strip-cartoon format. These cartoons are characteristic of the *Aha!* books; they are highly stylized drawings by Jim Glen, and feature characters such as Dr Zeta, the extraterrestrial scientist, and Mr Randi, the world-famous magician. I can imagine them either delighting or infuriating the reader. Intellectually, they provide a sort of pictorial commentary on the text which makes its reasoning more accessible, and gives the book a cheerful and whimsical atmosphere.

Aha! Gotcha should appeal to students and non-specialist readers who would be discouraged by a more formal presentation; at the same time even professional mathematicians may be glad to see their subject sketched in this ingenious way. Many of the paradoxes are not yet resolved — does the occurrence of a purple *cow* really provide support for the assertion that all crows are black? For those who wish to pursue such questions further, the book has a useful reference-list of further reading. Less dedicated readers will merely enjoy puzzling over the paradoxes and springing them on their friends. ☐

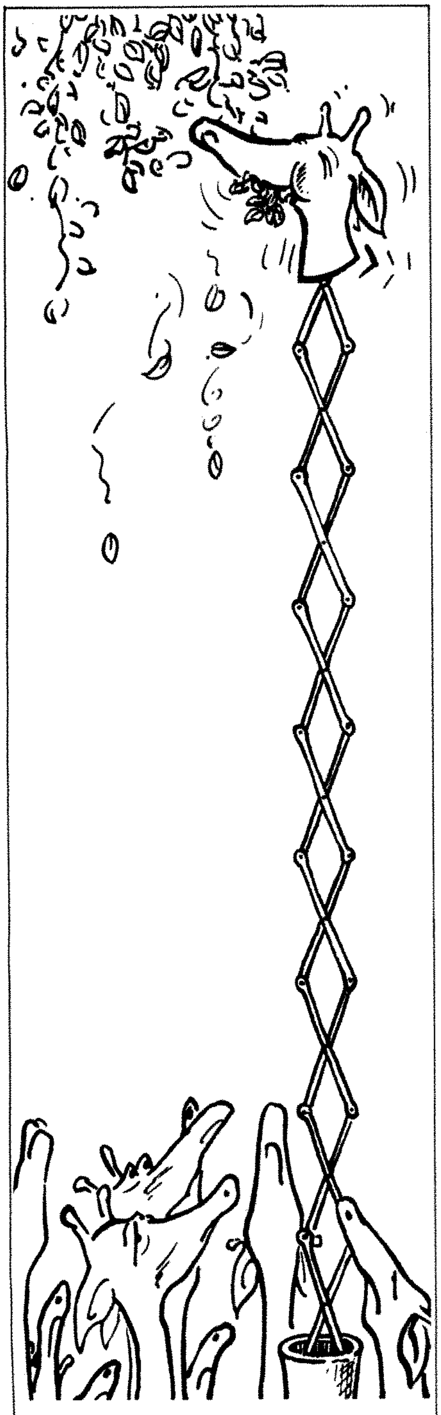
David Jones is a Guest Member of Staff with the Physical Chemistry Department of the University of Newcastle upon Tyne. His book, The Inventions of Daedalus, *derived from his weekly column in* New Scientist, *has just been published by W.H. Freeman.*

Darwin and evolution: the comic cut

J.S. Jones

Darwin for Beginners. By Jonathan Miller and Borin van Loon. Pp.176. Hbk ISBN 0-906495-95-4; pbk ISBN 0-906495-96-2. (Writers and Readers/W.W. Norton/Pantheon: 1982.) Hbk £7.95, $11.95; pbk £2.95, $3.95.

EINSTEIN, Marx, food, Freud, capitalism — and Darwin. These are some of the titles in a series of illustrated books "for beginners" which discuss complex subjects in a simple way using a mixture of cartoons and text. How does Charles Darwin emerge from his treatment as the thinking man's Andy Capp?



Stretching a point about evolutionary theory. One of Borin van Loon's illustrations in *Darwin for Beginners*.

The short answer is: remarkably well. Jonathan Miller gives us a concise and clear account of Darwinism, which is complemented by some two hundred crude but powerful illustrations by Borin van Loon. Darwin's predecessors, his life and the *Origin of Species* are covered in a body of text enough to provide only the preface for most books on evolution. We learn not only of the well-known elements of our hero's life, but also of neglected episodes such as Captain Fitzroy's early distrust of Darwin because the shape of his nose betrayed signs of laziness and hesitancy. The laziness — which provoked his father to exclaim that "You care for nothing but shooting, dogs and rat-catching. You will be a disgrace to yourself and all your family" — disappeared early, but the hesitancy remained for the rest of his days.

Darwin's lack of confidence and his hypochondria are often blamed on the effects of Chagas' disease (which he may have contracted in South America). Here a dramatic illustration shows him cowering before an infected mosquito — which is unfortunate as the vector is a wingless bloodsucking bug. There are many quotations from Darwin's writings, published and unpublished, including his musings on the advantages of a "nice soft wife on a sofa"; advantages which include, according to the accompanying cartoon, sharing a bed with Freud and Marx.

The treatment of Darwin's predecessors and his own work is outstandingly clear. We hear of Cuvier, to whom evolution was a process of stability interrupted by miraculous change, and of Paley, who saw in the perfection of living things the proof of an intelligent designer. That of neo-Darwinism and the "modern synthesis" is less successful, and shows signs of confusion. There is the compulsory nod towards neo-Cuvierism — or evolution by jerks as it is known to its critics — in which mysterious forces lead to evolutionary equilibria punctuated by rapid change, but nothing on neo-Paleyism, the view that all animal structure and behaviour is of necessity perfectly adaptive and is hence always a proof of strong natural selection.

Nevertheless, the book as a whole is a success. It can be recommended to biologists who have ceased to be entertained by evolution as well as to newcomers to the subject. Darwin, Doonesbury, Dennis the Menace: in this post-literate society to be immortalized in a comic strip is the ultimate accolade payable to a great mind. What next — a cartoon version of *Principia Mathematica*? ☐

Knocking about in the nineteen-eighties

Bernard Dixon

The Cult of the Expert. By Brian J. Ford. Pp.194. ISBN 0-241-10476-9. (Hamish Hamilton: 1982.) £5.95.

ONE of Dwight D. Eisenhower's more memorable remarks was that "public policy could itself become the captive of a scientific–technological elite". That forecast was underscored some years later by Dr Herbert York, Defense Department adviser to both Eisenhower and Kennedy, when he warned that the possible decision to initiate nuclear annihilation was passing "from the hands of statesmen to lower-level officers and ultimately computing machines and the technicians who program them".

Clearly, this is a theme, with parallels in fields as disparate as health and nutrition, communications and education, which is worthy of serious attention. Yet it has not been widely discussed — certainly not in books. Theodore Roszak's *The Making of a Counter Culture* (Faber & Faber, 1970) touched on the problem, but was more concerned with the domination of our society by the products and ideas of science than with the role of experts *per se*. So there certainly is an opportunity for a keen examination of specialists, their habits and attitudes, and their effect on the rest of us — citizens, consumers, customers, captives.

The Cult of the Expert appears at first sight to be such a book. It is (to take his conclusion first) Mr Ford's fleshing out of the following thesis:

> From the way you are born to the manner of your dying, great and earth-shattering decisions are taken behind closed doors by people who may well have closed minds. For the Expert all that matters is that they are seen to have a monopoly on power. Their long and meaningless words, elaborate and expensive apparatus stacked in high security buildings, the machines that they secretly know no more than anyone else how to use for the good of the people, are all part of today's power structure. The omnipotence of the Expert pronouncement and the unchallengeable right to spend huge sums of money gratifying a lust that evolved only to be gratified; these are the pattern for the future.

In support of these somewhat inelegant propositions, Mr Ford tells us at great length that experts employ contorted language. He provides many examples such as "mobility transportation system" for "car", quotes a passage we may have missed from *Private Eye* showing that the word "situation" has become comic, and uses a menu to compare "plain language" with French. He states that Ulcerative Dermal Necrosis ("as far as it means anything at all") really means that ulcers of dead skin form on the surface of fish, and he devotes an entire chapter to rules such as "never use one word where many will do".

Mr Ford recounts the banning of cyclamates, the N-ray story, the polywater affair, the Kammerer and Burt episodes, and the work of Stanley Milgram, to show science in a variety of bad lights. He says that an Expert could ban air, and explains that nitrogen and its other constituents can be dangerous. He criticizes new maths and decimalization (predicting that Experts will next want to divide the year into 100 parts). He then complains about bank cards and gives many examples of "the way in which the infectious enthusiasm for believing in computers has come close to harming our lives", before vouchsafing that there are innumerable other such examples. He gives pupils rules such as "Do just what the teacher says, and on no account argue" and opines that the purpose of a university is "to provide a closetted and confined period of indoctrination for malleable minds". Finally, with embarrassing innocence of the real world, Mr Ford tells us that "elaborate and expensive research institutes" are needed only for Experts to perpetuate themselves, and that libraries will go on paying inflated prices for journals.

Anyone setting out to survey such (some may think familiar) territory should decide whether their book is to be humorous or serious, and whether the aim is to flatter readers or make them feel uneasy. Mr Ford has done neither. He begins by taking a swipe at his readers' poor education and calling them "ordinary people", but then expects them to join in his sarcastic superiority. He enjoys his own knockabout fun but sours it all by being bitchy. He gets serious things wrong (the butter–margarine controversy was about the contribution of their respective fatty acids to coronary heart disease, not about which was more fattening) while trying to be witty by assuring us that Experts are above the law. And his publishers do not help by producing what they (presumably) intended to be a rib-tickling book with a dust jacket highlighting the author's "acid pen". Curious.

Mr Ford is not, I understand, a qualified scientist. So his words come with considerably less clout than those of, say, Sir Peter Medawar when he gently mocks some of his fellow experts. But then the very idea of Medawar writing ***this*** book is much funnier than anything Mr Ford has to say. □

Bernard Dixon, formerly Editor of New Scientist *and European Editor of* Omni, *is a science writer and consultant.*

Pictures, prose and a world of vegetation

Philip Stott

Green Planet: The Story of Plant Life on Earth. Edited by David M. Moore. Pp.288. ISBN 0-521-24610-5. (Cambridge University Press: 1982.) £12.50, $27.50.

THE many recent attempts of science publishers to blend the visually attractive with the academically acceptable have not always proved felicitous. Solid content has all too often yielded to the simply picturesque. One notable exception is Duvigneaud's splendidly gallic *La Synthèse Écologique* (Doin, Paris; 1974). This new encyclopaedia of plant ecology and geography is another.

There are two clear reasons for the book's success. First, the text, which has been skilfully compiled from the separate contributions of 30 specialists, dominates the book and is, in the main, both comprehensive and accurate. Secondly, the visual material is used to illustrate and exemplify the text rather than, as is so often the case, the words being mere adjuncts to pretty pictures. In addition, it is especially gratifying to welcome a general work on biogeography which acknowledges nearly all of the main traditions of the subject. In the seven well-constructed chapters, the encyclopaedia thus embraces the key aspects of ecology, of plant geography in its classical sense — meaning the study of the spatial distribution of plant taxa over the surface of the Earth — and of the role of man in nature. This last theme is perhaps the least satisfactorily covered and I was sorry to see no mention of the important applied textbooks of I.G. Simmons in the bibliography at the end of the book.

Obviously, in a survey of such breadth, there will be some blemishes. The term "ecology", for example, was not coined by the German biologist, Ernst Haeckel, in 1869 (p.21), but appears as early as 1858 in a letter of the American essayist and nature-lover, Henry David Thoreau; moreover, Haeckel himself first used the term in 1866. It is pleasing, however, to see both autecology and synecology adequately discussed.

Cladistics is well explained, as one would expect, by Heywood in his precise and useful entry on taxonomy and systematics, but nowhere is the possible phytogeographical significance of cladistic relationships explored. The closely related topic of vicariance biogeography is largely ignored, save for a short passage on vicariance written in a more traditional vein. It is also regrettable that many of the plant and vegetation distributions are still mapped on non-equal-area projections, which unacceptably exaggerate the northern latitudes, whilst the large and well-chosen glossary is occasionally somewhat opaque in its definitions.

But these are all quibbles. This encyclopaedia is both elegant and informative. The editor and his contributors are to be congratulated on providing what is really a colourful and modern Polunin (*Introduction to Plant Geography and Some Related Sciences*, published by Longman in 1960). It should prove of enormous value to both sixth formers and undergraduates, as well as to a wider readership of naturalists and botanists. ☐

Philip Stott is a Lecturer in Biogeography at the School of Oriental and African Studies, University of London, and author of Historical Plant Geography *(George Allen & Unwin, 1981).*

Other men's flowers, other men's gardens

Sandra Raphael

The Illustration of Plants & Gardens 1500–1850. By Vera Kaden. Pp.106. Hbk ISBN 0-11-290375-4; pbk ISBN 0-11-290331-2. (HMSO/Kraus Thomson: 1982.) Hbk £12, $25; pbk £6.95, $14.
The Origins of Garden Plants. By John Fisher. Pp.338. ISBN 0-09-463760-1. (Constable: 1982.) £12.95.

VERA Kaden's collection of pictures taken from botanical and gardening books in the library of the Victoria and Albert Museum made a good first impression on me by using a beautiful Ehret drawing of a lily — one of my favourites — to adorn its dust jacket. The source of the illustrations selected indicates that the books and manuscripts were chosen for aesthetic appeal rather than purely botanical interest, but such a limitation does not, of course, exclude most of the greatest plant books; nor, indeed, does it detract from the book's contents.

A short introduction, sparingly decorated with black-and-white illustrations, canters briskly through a potted history of garden design, with excursions to provide necessary details of herbals and flower books and the processes by which they were illustrated. There is also a brief account of floral symbolism.

The remaining two-thirds of the book is made up of plates, about half of them in colour, all with descriptive captions. The arrangement is more or less chronological, starting with the earliest woodcuts of plants from the late fifteenth century and ending with a couple of plates from Victorian albums of flower paintings. The plants and the gardens go hand in hand, with pictures to show changing tastes in design, from the enclosed mediaeval garden to architectural Italian ones, formal patterns from France and the English style of landscaping. Nearly all the colour plates, reasonably enough, are devoted to the work of the flower painters, with Maria Sibylla Merian, Ehret, Redouté and Franz Bauer representing the greatest of them. Altogether the book makes an attractive guide for those taking their first steps in garden history.

From The Illustration of Plants & Gardens 1500–1850

John Fisher's book, *The Origins of Garden Plants*, also offers background information to the curious gardener, in this case on the subject of plant-hunting and the introduction of some of the botanical immigrants now comfortably settled in the British Isles. The book starts with a couple of chapters on the native plants of Britain before going on to those cultivated for medicinal and other purposes in mediaeval times. Then we are launched into the search for decorative plants, which very often ran parallel with the exploration of new colonies. Almost every part of the world has been visited by amateur or professional plant-hunters, with obvious consequences in the range of plants now available to us — the rhododendron belt of the Home Counties would not have been possible without Hooker's Indian journeys and the Chinese collections of several French and British explorers; and several of the species of conifer covering all too many of our hills are the descendants of the North American discoveries of David Douglas and his contemporaries.

Collectors in Europe began with attempts to identify the plants described by classical writers. The seventeenth century brought the first great wave of introductions from the New World, many (including *Tradescantia virginiana*) via the gardens of the Tradescants, father and son. The French in Canada and the southern part of the continent sent back plants to Paris, the Spaniards in South America to Madrid. French missionary priests, particularly in China, sent home plants as well as the first report of the giant panda.

In the late eighteenth and early nineteenth century, Sir Joseph Banks, First as a collector, later as the impresario of other men's travels, commanded the field. His patronage, allied with that of the Royal and Horticultural Societies and Kew Gardens — all three institutions firmly under Banks's wing — sent professional collectors across the globe; South Africa, Australia, China and Japan were all areas in which he was interested. Later other patrons or nurserymen financed major expeditions, a pattern that lasted to relatively recent times and the journeys of Ludlow and Sherriff and of Kingdon-Ward. Now the flood of new plants has slackened a little and efforts are being made to prevent the loss of older species driven into neglect by the vagaries of horticultural fashion.

The subject of Mr Fisher's book must appeal to any gardener with the slightest interest in the history of the plants he or she grows. The text, however, is not always accurate; nor are the captions to the illustrations. No one reading the book would guess that the Chelsea Physic Garden still survives, although its future seems once again to be in jeopardy. And it is said that Robert Brown, his Australian travels over, was "afterwards librarian of the Linnean Society". He did not stay in that position, though, for he was Banks's botanical heir, an eminent scientist in his own right and eventually President of the Linnean too.

From The Illustration of Plants & Gardens 1500–1850

The author notes of John Bartram, an eighteenth-century Quaker naturalist living in Pennsylvania, "His spelling remained consistently unreliable". A similar warning is needed here, for Mr Fisher's book appears to have escaped both copy-editing and proof-reading. Spelling in English and Latin is equally eccentric: even dates are often wrong. Let the buyer enjoy this pleasant book, but also beware of trusting the accuracy of the details. ☐

Bees for science and bees for keeping

John Powell

Bees and Mankind. By John B. Free. Pp.155. ISBN 0-04-638001-9. (George Allen & Unwin: 1982.) £9.50, $17.95.

DR JOHN Free is internationally acknowledged as an authority on bees and pollination; his published work in the scientific literature is extensive. Any book from such a source is therefore bound to be looked upon as of some importance in beekeeping circles.

It is interesting to note that of Dr Free's books to date, half have been written for children and it is evident that he has mastered the art of expressing a complex subject in a straightforward and lucid manner. In confirmation of this, *Bees and Mankind* is a fascinating and easily readable work, though its structure is unusual. The book is split into three parts entitled "Bees: Solitary and Social", "Honeybees" and "Beekeeping: Past and Present". The reader, however, is more likely to regard the text as divided into two.

Parts I and II together provide a brief account of two selected solitary bees, *Osmia rufa* and *Megachile rotundata*, and a more detailed treatment of bumblebees and honeybees. Each chapter is broken into short sections, each headed by a quotation from such divers sources as Virgil and J.G. Whittier. It is the sharp contrast between the cool text of Dr Free and the colour of some of the poetry that provides much of the charm of this book, though I found it took some time to get used to it. This then is not a book to dip into — at least not at first acquaintance.

RETARDED
ACTION-AT-A-DISTANCE

The Change of Force with Motion

G. BURNISTON BROWN

Ampère's laws and radio experiments are used to find the velocity and acceleration terms in the force-formula for two charged particles. When this is applied to uncharged particles in a spherical Universe, the origin of Newton's First and Second Laws, the force of inertia, the gravitational red-shift, and the perihelion advance of the planets is made clear. At very high speeds, the corrective term found by Bucherer to be necessary for agreement with experiment, is used as a factor in the force-formula. In this way a unification of dynamics and electromagnetism is attempted.

This book promises to be one of the most profound new treatises on the fundamentals of physics in this generation ... a totally new approach to physics, one that returns physics to the business of the "causes of sensible effects"

Circle No.32 on Reader Service Card.

There is a distinct change of style when we enter Part III, effectively the second half of the book, and move from the strictly factual material to a narrative of man's relationship with bees over 9,000 years, from primitive honey-hunting to the sophisticated mechanization of the late twentieth century. This must be one of the most complete accounts available and John Free's wide experience of the bee species involved is evident in the way he has been able to make a coherent whole from the often fragmentary evidence. There is, too, more than an interesting story here; in their unobtrusive way bees have had a profound influence on man's social, religious and cultural development.

Like the bees themselves, the sting of the book comes in the tail. The closing pages deal with the influence and availability of pollinating insects on agricultural production, both in intensively farmed areas and in developing countries.

The book is liberally illustrated and is beautifully set-out and produced. Although the subject matter is vast there is throughout an element of speculation which binds the whole together, be it the socialization of bees or man's manipulation of that social organization. It would be a pity if *Bees and Mankind* remained solely within beekeeping circles; it could be read profitably by all who are involved in conservation and planning, agricultural development, international aid programmes and anthropology. ☐

High in Africa

Margaret Sharman

Kilimanjaro. By John Reader. Pp.84. ISBN 0-241-10683-4. (Elm Tree, London/Universe: 1982.) £12.95, $25.

KILIMANJARO is not only Africa's highest mountain, and so a magnet for climbers, it is also an ecologist's delight. Within a few miles one finds tropical forest, alpine flora, near-desert, glaciation and the world's biggest volcano. Such variety provides scope for the excellent photographs, ranging from majestic landscapes to haunting close-ups, with which John Reader adorns his record of one man's pilgrimage to Kilimanjaro.

One usually sees the mountain for the first time as a backdrop for the migrating herds of the Serengeti Plain, the elephants of Tsavo, or even, on a clear day, the ex-colonial suburbs of Nairobi, over 100 miles away. It rises from the burning heat of the thorn savannah, and it is no wonder that the reports of missionaries Krapf and Rebmann in the mid-nineteenth century were rejected as the imaginings of fevered brains and poor eyesight.

Yet tales of snow-capped mountains in Africa were not new. As an introduction to the highly personal account of his first climb, the author traces the story through the centuries, as Europeans overcame the obstacles — adverse geographical conditions, slave traders and the spears of tribesmen defending their homeland against white men bent on "discovering" Africa. (I am dismayed, incidentally, to find that the kink in the Kenya–Tanzania border is not the result of Queen Victoria giving Kaiser Bill the present to end all presents.) African legends, too, there are in plenty; and tales of those who were intrepid enough to brave the "fiery beings" and the fingers that "died", to obtain samples of "the silver-like stuff [which] when brought down in bottles, proved to be nothing but water".

Climbing the mountain is one of the things Westerners who live in East Africa aim to do "one day". It is everybody's mountain in that, while it is climbable without expertise, the twin peaks of Kibo and Mawenzi provide severe challenges, some of which are here described with concomitant gruesome tales of misadventure.

The snows of Kilimanjaro are melting rapidly (the ice has been in retreat since *c.*1700), and the melting process is responsible for the fantastic ice edifices which are among the most striking images in the book. Lower down in tropical splendour are the giants — the lobelias, and the groundsels which grow up to four metres high and may be 100 years old. How plants withstand temperature extremes and at the same time cope with intense ultraviolet radiation and the threat of being exhumed by solifluction is explained in the last section of the book.

Near the mountain's summit are found cryptozoic spiders, and crystallized butterflies which have been blown up by the "anti-trade wind" — a wind which explains the conventional picture of a snow-white summit riding high on a cloud layer and apparently completely detached from the earth below. This is the one photograph which every tourist takes home, even if only on a postcard, and which John Reader omits. But with 82 colour plates one cannot cavil at that. Here is an attractive and very readable book.

Margaret Sharman is a freelance editor specializing in books on African history.

Half and half in the national parks

Brian Bertram

A Field Guide to the National Parks of East Africa. By John G. Williams and Norman Arlott. Pp.336. ISBN 0-00-219215-2. (Collins/Stephen Greene Press: 1982.) £7.95, $29.95.

LIKE ALL Gaul, this handy field guide is divided into three parts. The first part surveys the national parks, game reserves and other faunal areas of Kenya, Tanzania and Uganda, the second is a guide to the larger mammals and the third a guide to the commoner birds of East Africa.

Unlike all Gaul, the standard of the three parts varies widely. The 70 pages on the mammals are well-presented and accurate; they are in effect the same as in the original 1967 version of this field guide. With the help of 13 pages of illustrations, they enable the visitor to identify almost any mammal he is likely to encounter. The 92 pages on the commoner birds are also good, and are the completely new part of the book. They replace the section in the previous edition which dealt with the rarer birds, and instead provide a condensed version of its companion volume on the birds one is more likely to see. Fifteen pages of effective colour illustrations help in the identification.

But as for the remaining part, "Oh dear" was my reaction. The opening 160 pages on the national parks and other wildlife areas are absolutely riddled with mistakes, and are going to mislead a great many people. Partly this is because they are hopelessly out of date, and have not been changed from the previous edition. Thus, to pick out just a couple of examples, the area of Meru National Park is now less than half the area John Williams states, and the "motor boat available for anyone wishing to explore the country from the rivers" was actually burnt to ashes at least a dozen years ago.

Other errors abound on the maps, caused partly by some careless re-drawing of long out-of-date maps. Thus roads (in Tsavo) and boundaries (in Amboseli) are often in the wrong place, and lodges are omitted (in Serengeti) or misplaced (in Tsavo). Even whole reserves are misplaced — one is shown over 200 km away from where it actually is. Advice on routes is often wrong and details in the species lists for the parks are faulty; for example the abundant hippo is omitted from Tsavo (despite a successful film about them there), and Patas monkeys have not been seen in Meru by anyone who has worked there for long. And so on.

This is very sad, because there is a wealth of knowledgeable people in East Africa who could have weeded out almost all of these mistakes, and made the book far more useful. As it is, one has to say "Don't trust the first half of it". But there is no other comparable guide, so if you are going to East Africa you had better get hold of it, warts and all. And take with it a pinch of salt and some proper maps. □

Brian Bertram is Curator of Mammals at The Zoological Society of London.

Private lives

John R. Krebs

The Discovery of Animal Behaviour. By John Sparks. Pp.288. ISBN 0-00-219061-3. (Collins/Little, Brown: 1982.) £12.95, $24.95.

FOLLOWING along the now well-used trail opened up by *Life on Earth, The Discovery of Animal Behaviour* is the book of the television series recently shown on BBC2. The text follows almost verbatim the script of the programmes, and although well written it loses some of its impact when not accompanied by the film. But pictures there are in plenty; every second page is a double-sided colour plate of high quality.

For those unfamiliar with the series, the book is essentially a history of ethology, highlighting the contributions and circumstances of key figures from the middle ages to the 1960s. The "stars" include Ray, White, Leroy, Darwin, Romanes, Spalding, Loeb, Watson, Skinner, Pavlov, Lorenz, Tinbergen and von Frisch, a fairly uncontroversial list. In spite of its title, the last two chapters of the book (covering the mid-twentieth century) are almost exclusively about ethology and sociobiology: psychologists fade out after Skinner and Harlow.

Those hoping to gasp at arcane marvels of animal behaviour or to be enlightened about the big issues in present-day ethological research may be disappointed, for this is as much an account of the people as of their subject. It is hardly gripping stuff, especially for those not familiar with animal behaviour; after all, most naturalists are men of quotidian habits.

One of the nice features of the book is the way in which the discoveries and attitudes of individuals are related to their personal circumstances. For many the stimulus and opportunity to study animal behaviour was linked with relaxing country residences — a mill by an Austrian lake, a rambling house close to the Danube, a country cottage at Dunskaith; in stark contrast, we are told that the theoretician W.D. Hamilton did much of his thinking while waiting at Waterloo Station!

Another recurrent theme is how easily scientists were led to generalize their findings to an unreasonable point. Loeb, the discoverer of phototaxis considered whether the human mind could be explained in terms of taxes and tropisms; Romanes asked whether spiders might appreciate music; and Schelderup-Ebbe, the man who discovered dominance hierarchies, subsumed the relationship between God and the Devil in his account of social organization. It is easy to smile, but less easy to see whether or not one has one's own musical spiders. □

John R. Krebs is Lecturer in Zoology at the Edward Grey Institute and E.P. Abraham Fellow of Pembroke College, University of Oxford.

And the gentlemen went there two by two

Bernard Stonehouse

Voyage Through the Antarctic. By Richard Adams and Ronald Lockley. Pp.160. UK ISBN 0-7139-1396-7; US ISBN 0-394-52858-1. (Allen Lane/Knopf: 1982.) £8.95, $13.95. *Antarctic Wildlife.* By Eric Hosking and Bryan Sage. Pp.160. ISBN 0-7099-1215-3. (Croom Helm/Facts on File: 1982.) £12.95, $22.95.

ANTARCTICA and the Southern Ocean are among the few remaining bastions of wildlife, though with a long history of depredation at the hands of human beings. Southern fur seals were hunted almost to extinction on the peripheral islands in the eighteenth and nineteenth centuries, and whale stocks devastated in the present century. Elephant seals and even penguins were boiled by the thousand for the golden oil in their blubber. Now the killing of the larger animals has almost stopped; attention turns to harvesting the fish and krill that will form man's final bonanza from the Antarctic.

For many years scientists and their support teams had sole rights of travel in the far south. Today tour ships are regular visitors, loaded with enthusiastic passengers who saw Alaska last year, the Galapagos the year before, and are now doing Antarctica. Tourists on the hallowed ground where Scott, Amundsen and Byrd once stood? Yes, and good luck to them. Nowhere in the world is the scenery grander and less spoiled by human artefacts; nowhere do seals and seabirds gather in more spectacular concentrations; and nowhere are wild animals more readily approachable by nature-lovers with camera, notebook and wide-eyed wonder. The two books reviewed here arose from tours laid on by Lindblad Travel, one of the earliest operators to brave the fury of stormy seas, elitist scientists and anxious administrators to take ordinary people (well, ordinary *wealthy* people) to the Antarctic. As a result, thousands have seen the southern wonderland who would otherwise have been excluded, and there are correspondingly more who can write about it, read about it and, if necessary, root for it from first-hand knowledge.

Voyage Through the Antarctic, the smaller and cheaper volume, is the narrative of a journey from Tierra del Fuego to Stewart Island, New Zealand, via the South Shetland Islands, Antarctic Peninsula, Peter I Øy and the edge of the Pacific sector pack ice, calling at McMurdo Sound, skirting Cape Adare and the Balleny Islands, and visiting Macquarie and Campbell Islands on the homeward run. Two generations ago this voyage would have been regarded as hazardous in the extreme; even now it is a voyage that polar scientists (myself among them) would be glad to experience for the research opportunities offered. Yet this and other trips like it are the stock-in-trade of tourist operators these days. Richard Adams, naturalist, novelist (*Watership Down, Shardik, The Plague Dogs*) and RSPCA luminary tells the plain tale, which naturalist and writer Ronald Lockley (*Man against Nature, Orielton, Ocean Wanderers*) embellishes with italicized passages of concentrated natural history.

This may well have been a practical way (perhaps the only way) of combining the talents of two celebrated writers who live far apart and write in widely-diverse idioms. For me the device fails; the two voices sing in different keys. Both authors are self conscious, Adams, the jolly tourist, Lockley, lyrical–authoritative; both have written far better, and neither rises fully to what could and should have been a splendid occasion. Peter Hirst-Smith's photographs too are disappointing. The few pages of colour glow excellently, but the many black-and-white prints spread through the text could have been selected more rigorously and printed less muddily; the best are fair, and the worst have a potato-print quality that does them no justice. But this is a good adventure story, with a lot of information and a deal of enthusiasm for Antarctica and its animals that make the book worthwhile.

Antarctic Wildlife is for me a much more satisfactory book, larger and almost fifty per cent dearer, but a far better production all round. This is not the story of a voyage; it is an account — indeed a celebration — of Antarctic life, seen through the perceptive eye of Eric Hosking and discussed in scholarly but readable vein by Bryan Sage. The Old Master has lost none of his touch; these are superb photographs, printed to a high standard in both colour and black-and-white. I cavil only at a designer who on occasion lets the central gutter spoil the layouts unnecessarily. The seven chapters cover the historical background, continental, maritime and subantarctic ecology, and the life histories of penguins, albatrosses, other birds and seals; there is a final chapter on wildlife photography that many will find valuable. *Antarctic Wildlife* is an authoritative and beautiful volume, a book fit to match its subject. □

Bernard Stonehouse is at the Scott Polar Research Institute, University of Cambridge, and editor of Polar Record.

Poles apart

Wildlife in the Arctic, specifically the polar bear, is the subject of *Lords of the Arctic* by Richard C. Davids with photographs by Dan Guravich. The book is an account of scientific observations, conservation problems and the authors' experiences in their search for this elusive animal. Published by Macmillan, New York, *Lords of the Arctic* costs $29.95.

The natural history of mammals anew

I.J. Linn

Mammals in the British Isles. By L. Harrison Matthews. Pp.208. ISBN 0-00-219738-3. (Collins: 1982.) £10.95.

A NEW title from the prolific pen of Dr Harrison Matthews is always a significant event in the world of theriology; and this *is* a new title, not merely a new edition of his earlier book, *British Mammals,* in the same *New Naturalist* series.

As both author and publisher are at pains to point out, the tremendous flowering of theriological literature which has taken place in the past 20 years or so has enabled the author to dispense with much of the basic introductory material which was necessary in the older book, and to follow through a specific line of thought with simplicity and clarity. That line is the one which amateur naturalist and professional zoologist alike contemplate with wonder and delight, namely the extraordinary detail and perfection of the adaptations of animals, in this case British mammals, to the environments in which they live. It is the line of thought which has given us the academic disciplines of sociobiology and behavioural ecology, and it also generates many of the questions which thinking people of many differing ages and backgrounds ask of biologists — questions which are often very difficult to answer. This book will help all of these people.

Dr Matthews lays a firm foundation by spending most of the first third of the book reviewing the geological, climatic and human influences which have shaped the range of habitats available to British mammals. He then goes on to write lucidly and effectively about the various facets of ecology and behaviour which define a mammal's adaptivity, presenting hard scientific information and modern theory in a palatable and easily absorbed manner.

The book as a whole is spiced by Dr Matthews's trenchant and perceptive comments upon humanity, past and present. It is an excellent introduction to the natural history of British mammals for anyone, amateur or professional, who is interested in real animals in the real world.

Ian Linn is Senior Lecturer in Biological Sciences at the University of Exeter, and a founder member of the Mammal Society.

Birds from the kitchen window . . . and much further afield

John Andrews

THE KITCHEN window is the starting point for many people's interest in birds — an interest which they may never take beyond the front gate. **The Garden Bird Book,** edited by David Glue (Macmillan, London, £7.95), is right up their street. Compiled by the British Trust for Ornithology, its aim is to help people encourage birds into their lives by providing suitable food and shelter. It contains lots of practical advice applicable to the small suburban garden as much as to the fortunate minority whose spacious grounds attract woodpeckers and water rails. More than that, the text is thoroughly interesting, and packed with insights into the lives and survival strategies of common birds. Well-illustrated, this is certainly a book to enthuse the garden bird-lover and perhaps encourage forays further afield.

Anyone who does venture the transition from bird-lover into bird-watcher must soon attempt to choose from a plethora of field identification guides. Little has been added to the current choice by John Gooders and Terence Lambert's **British Birds** (Collins/Stephen Greene Press; £12.95, $39.95). On the one hand, Lambert's illustrations though aesthetically pleasing are of little help to field identification: indeed, as printed, some of the colour tones are positively misleading. On the other hand, John Gooders' text is largely field-identification material inappropriate in a book which might fit the parcel shelf but certainly not an anorak pocket. In style and format, the book is very reminiscent of the Readers Digest/AA *Book of British Birds* published in 1969 which remains the more readable and entertaining volume.

Field identification skills usually depend less on feather-perfect knowledge of plumage than on knowing where and how different species comport themselves — just as most people recognize acquaintances at a distance without any ability to describe them in detail. For the fairly inexpert, **Birdwatching on Inland Fresh Waters** by Malcolm Ogilvie (Severn House, £8.95) provides this kind of helpful information on identification and basic ecology for a group of habitats rich in birds and accordingly popular with birders. Opening with a description of Britain's freshwater habitats, the author, who is on the Wildfowl Trust staff, moves on to discuss many aspects of wetland bird adaptation and behaviour, and concludes by explaining some of the current research and conservation work directed at these birds.

Strangely, many bird-watchers seem happy to go through life without ever understanding how the objects of their identification skills actually function. For those who are moved to do so, a good and not overly technical account is provided in the book **How Birds Work** by Ron Freethy (Blandford/Sterling; £8.95, $15.95). The author has evidently reviewed the current literature to produce an up-to-date explanation of opinion on evolution, structure, flight, respiration, feeding, the nervous system, breeding, migration, behaviour and distribution. Unfortunately, a rag-bag of illustrations adds nothing to the book's appearance and little to its information.

One area of common ground between bird-lover, bird-watcher and the scientific ornithologist (pompous fellow!) is the almost universal appeal of birds of prey. In Britain, a peregrine falcon is perhaps *the* bird to see on a day in the field. Following the crash in peregrine populations due to organochlorines, work on captive breeding as a conservation technique was developed in the United States by Dr Tom Cade, Professor of Ornithology at Cornell. Now, in **Falcons of the World** (Collins/Cornell University Press; £15, $38.50), he summarizes present knowledge not only of peregrines but of the entire falcon genus. The first quarter of the book is a general review of falcon biology and ecology, the bulk of the text comprising essays on each of the 39 species with handsome plates by David Digby, whose double spread of a gyr falcon striking at a ptarmigan is stunning. Though a glossy, large-format work, this is not to be dismissed as a coffee table volume: it is a scholarly and appealing account of a group of birds which, as Cade says, "more than any other combines form and function in a perfection that can hold men in spellbound wonder".

Study of a heron, by Eric Ennion. The illustration is taken from *The Living Birds of Eric Ennion,* a collection of drawings and paintings which displays the late Dr Ennion's remarkable and varied talents as writer, ornithologist and artist. The book includes a commentary by John Busby and is published by Gollancz, price £9.95.

Though birders have become increasingly well-travelled in the past decade, most would be hard pressed to know where to look for cotingas. The family, which includes bell-birds, umbrella birds and the cock of the rock (ah! now you know) contains about 65 species, mostly specialized fruit eaters, from the forests of South and Central America. In **The Cotingas** (Oxford University Press/Cornell University Press; £30, $45) David Snow attempts to provide the first comprehensive account of the group, drawing on his own studies as well as on the work of others. Though hardly likely to appeal to a wide readership, the book is certainly of interest to those studying avian courtship behaviour and, as the author sadly remarks,

> if it stimulates further fieldwork and encourages wider interest in a family of birds that suddenly, in the last thirty years, after millions of years of evolution, are as threatened as the forests in which they have evolved, it will have achieved another of its purposes.

Closer to home, there is concern for a number of species which show recent declines. One is the barn owl and it is opportune that a major monograph has now appeared. **The Barn Owl** by D. Bunn, A. Warburton and R. Wilson (Poyser/Buteo; £12.60, $32.50), is based on the equivalent of 38 years of field work between 1963 and 1982, covering virtually all the habitat types used by the species in Britain. The authors' findings are compared with those of other workers world-wide — for the barn owl is perhaps the most widespread land bird in the world. A readable style, good presentation and illustration make the book a model of its type. Once again, ornithology owes a debt to the amateurs who "lose inordinate amounts of sleep . . . . get eaten alive by a varied assortment of biting flies . . . . and spend long hours when absolutely nothing happens".

It was amateurs too who undertook the three years' field work which produced in the mid-1970s the Register of Ornithological Sites. This ambitious project, run by the British Trust for Ornithology, sought to identify and evaluate as many as possible of the ornithologically important sites in the United Kingdom. Inevitably, it fell short of comprehensive coverage but it has provided conservation planners with a valuable aid for individual site protection, a yardstick and methodology for site evaluation, a pointer to habitat types or areas requiring further coverage and, last but not least, a basic evaluation of the overall resource now published as **Bird**

Habitats in Britain (Poyser/Buteo; £13, $35). The author, Rob Fuller, was responsible for organization of the national survey and he has drawn not only on its results but on many other sources to describe the composition of bird communities in different habitat types: he also comments on the pressures from current land-uses, notably agriculture and forestry which are the major modifiers of habitats and thus the greatest threat to a number of British species.

A mapping exercise of a different character is represented by Colin Harrison's **Atlas of the Birds of the Western Palaearctic** (Collins/Princeton University Press; £12.95, $25) which shows the summer, winter and resident distribution of all species normally occurring in Europe, North Africa and the Middle East. The text gives accounts of each species' status, climatic range, typical habitats and sites and there are pleasant, if rather irrelevant, half-tone drawings of the species concerned on each page. The layout and presentation are clear and the work provides a partial up-date of Voous' masterpiece, *Atlas of European Birds*, now 20 years old. Perhaps inevitably in such a complex exercise, there are mapping errors but, used with care, the book will be of value, not least to the select band of birders who seek to pursue their hobby wherever birds themselves go. □

John Andrews is Head of Conservation Planning at the Royal Society for the Protection of Birds, Sandy, Bedfordshire.

Africa's avifauna

C.M. Perrins

The Birds of Africa, Vol. 1. By Leslie H. Brown, Emil K. Urban and Kenneth Newman. Pp.536. ISBN 0-12-137301-0. (Academic: 1982.) £53.40, $99.

NO WORK covering the birds of the whole of Africa has been published for over 20 years. *The Birds of Africa* is intended to remedy this state of affairs, and when completed will comprise at least five volumes (with the possibility of a further one to include the birds of Malagasy and the Indian Ocean).

This, the first volume, deals with 10 orders of non-passerine birds from ostriches to birds of prey, some 270 species in all. It starts with 31 useful pages of general information on the geology, climate, geography and habitats of Africa, and with an introduction to the avifauna, the number of species involved and their migrations.

In the main part of the book the information given for each species is fairly standard handbook material, with details of range and status, description, field characters, voice, general and breeding habits and food, together with a distribution map and one or more pictures on the colour plates. On average some 1½ pages is allotted to each bird, though a few well-known species (such as the ostrich) get as many as five pages and a few of the vagrants only a few lines. Throughout the book the writing is clear and informative, and emphasizes field biology, especially ecological and behavioural studies, the latter often including line-drawings to amplify the text.

Although the standard of presentation is high, there are some shortcomings. For instance the distribution maps raise a few problems. Many in other handbooks show summer and winter ranges. This is more difficult when dealing with African birds because different areas experience such very different seasons. Ideally, however, it ought to be possible to depict breeding and non-breeding distributions and it is a little disappointing that this has not been done, except in a very few cases. In addition there is some inconsistency — albeit minor — in the treatment of distributions of the birds of offshore islands and in mapping bird distributions in Malagasy.

Bird books often stand or fall by the quality of their illustrations, but here the plates — by Peter Hayman and Martin Woodcock — are well up to standard. Some of the paintings are on the small side; in the extreme case there are over 70 birds on a single page. However on the whole they are acceptable because of the large format of the book, and as a group they succeed remarkably well in being both accurate and aesthetically pleasing. For most species there are at least two pictures showing the different sexes or summer and winter plumages; in addition there is often a painting of a young bird.

One minor worry concerned the amount of space available for each species. The dust-jacket states that there will be a further three volumes. However, this first volume includes only about 270 of the 1,850 or so species recorded in Africa. Hence the remaining three volumes would have had to cover 1,600 species, or twice as many per book as Vol.1. Even granted that this volume contains many of the better-known birds, such as the ducks and birds of prey, this would have been difficult. Fortunately the publishers have recently decided that there will be at least one further volume; this will ease things considerably.

The Birds of Africa, an immense project, was the brain-child of Leslie Brown who sadly died before this volume was completed. One very much hopes that the other authors will maintain his drive since the completed work will be a valuable contribution to ornithology. □

A world of far away and long ago

Andrew Hill

The Historia Naturalis of Pliny the Elder. By Joyce Irene Whalley. Pp.46. ISBN 0-283-98905-X. (Sidgwick & Jackson: 1982.) £6.95.

PROPPED between two slaves poor Pliny died, while the pumice of Vesuvius fell about him. It was his constant search for facts that led to this early demise, a compulsion that had produced a number of books on a range of subjects, now all lost but for the encyclopaedic *Historia Naturalis*. This work justly purported to encompass ". . . the world of Nature, or, in other words, Life . . .", and assembled what Pliny calculated as 20,000 facts, culled from 2,000 other books and his own experience. Including places, peoples, animals, plants, geology, medicine, painting, it provides a rich view of the world in the first century AD. This is a significant view, for it was one that with all its faults and pseudodoxies dominated Europe through the Middle Ages and extended its influence to more recent times.

Joyce Whalley's fascinating work is rather less ambitious, being intended primarily as a picture book. In the 1460s Giuliano Amedei illustrated a manuscript of Pliny with elaborate historiated initials for each of the 37 books or chapters. These depicted scenes related to the subject matter, and occasionally are as fanciful as parts of the text. One, for instance, shows a varied assemblage of humanoids, including the rare umbrella-foot tribe who, disposing themselves upon their backs, avoid the sun's glare through the protection afforded by the shadows of their substantial feet.

Some of these beautiful illustrations, highly ornamented in white vine decoration, resemble secular aspects of the contemporary books of hours, being lively and realistic treatments of everyday fifteenth-century activities. Many also reflect Pliny's patchy accuracy: elephants have lions' feet, and even more readily observable insects have eight or more legs.

Amedei comments visually on Pliny; Joyce Whalley comments on them both. Short descriptive sections opposite each plate indicate their significance, giving a necessarily brief account of the appropriate chapter and selecting phrases, practices and beliefs that have some particularly modern association. This pleasant and enjoyable book provides a vivid and instructive glimpse of the world through earlier eyes. It is also an enticement to explore in more detail the complete work, forming a gentle introduction to the cosmos and nature of Pliny. □

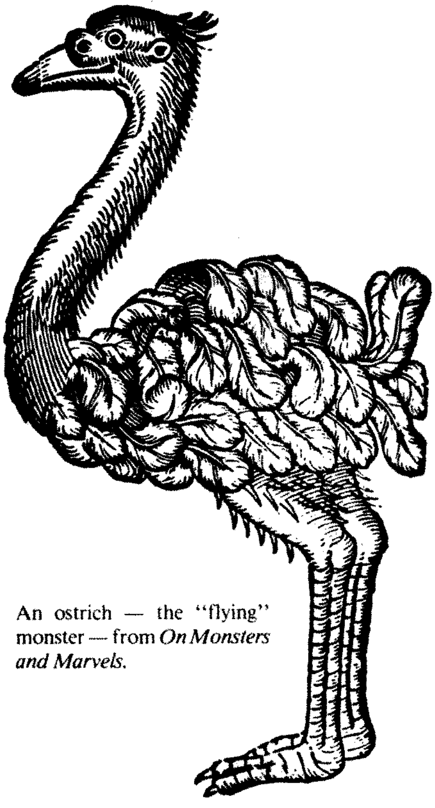
Creatures of fact, creatures of myth from the sixteenth century

Bernard Wood

Ambroise Paré: On Monsters and Marvels. Translated and introduced by Janis L. Pallister. Pp.224. ISBN 0-226-64562-2. (University of Chicago Press: 1982.) $20, £14.

IF ANY man has claim to be regarded as the Father of Modern Surgery, it is Ambroise Paré, the greatest of the Renaissance surgeons. Born of a humble family in 1510, Paré became apprenticed as a barber-surgeon, eventually moving to Paris in 1533. He gradually freed himself from his hair-cutting duties and was appointed *aide-chirurgien* at the Hôtel-Dieu, and by the age of 30 had qualified as a barber-surgeon.

Paré's training was essentially practical rather than scholastic; like many distinguished surgeons, he learned much of his craft on the battlefield. His first experience of war was the attack on Turin by Francis I in 1537. He quickly put his experience at the Hôtel-Dieu to good use, and concluded that the application of boiling oil frequently impeded rather than facilitated the healing of missile wounds. His campaigning days ended in 1559, but from then until his death in 1590 Paré managed to remain close to the crown and true to both the art and science of surgery. He advanced treatments as diverse as those for hernia and bone fracture, and devised enduring instruments such as forceps for clipping arteries.



An ostrich — the "flying" monster — from *On Monsters and Marvels.*

Of all his legacies, however, perhaps the richest is the breath, wisdom and humanity of his writings. He wrote not in Latin, but in Old French, and his willingness to discuss any matter on which he had practical experience did not always endear him to his peers. The 1575 edition of his collected works particularly outraged Estienne Gourmelen, the Dean of the Faculty of Physicians in Paris. Paré's reply to Gourmelen was trenchant and typical: "Dare you teach me Surgery, you who have never come out of your study? Surgery is learned by the eye and the hands. You mon petit maître, know nothing else but how to chatter in a Chair".

It is an indication of Paré's prodigious energy that *Des Montres et Prodiges,* first published in 1573, was the nineteenth in his series of surgical writings. Though the work had earlier between translated into Latin and thence into English, this edition is the first to be prepared by translating the original French into English. Janis Pallister's translation preserves the earthiness of the medical literature of the time — the directness and freshness of Paré's prose is in clear contrast to that used in modern-day texts where a leaden style is too often mistaken for scholarship. The dust-jacket claims that the edition includes a scientific commentary. It is true that a physician and a biologist provide notes and suggest identifications or diagnoses of what Paré describes, but these are modest and often merely expand on an earlier commentary by Paul Delaunay.

On Monsters and Marvels, a delightfully whimsical book, is divided into four parts. The first (and much the largest) section is devoted to human and animal monstrosities. Some of these animal "monsters" are descriptions and reports of creatures which are recognizable; others are clearly creatures of the imagination. The first chapters, devoted to human congenital and birth defects, make fascinating reading when one considers the period when the book was written. They include a description of what appears to be an example of the testicular feminization syndrome, and picturesque accounts of malingerers and patients suffering from calculi.

Flying, terrestrial and celestial monsters occupy the last three chapters. The "flying" monster turns out to be the ostrich and the terrestrial one the elephant, and the structure and habits of both animals are described and discussed: the observations on the ostrich were based on a skeleton of one of three ostriches kept by King Charles. The suggested identifications and scientific notes are useful but not infallible. For example a stone "under the tongue" of Captain Augustin, Engineer to the King, was almost certainly in the duct of the submandibular gland and not in the duct of the parotid as is claimed in the commentary.

It may seem to us that a book which dwells on monsters and marvels was an idiosyncratic choice for a surgeon. However in Paré's time such books were in vogue, and we must be grateful to Janis Pallister for making this curious and beguiling work more widely available. ☐

Bernard Wood is Professor of Anatomy at The Middlesex Hospital Medical School, University of London.

Fragments of the past

John Sutton

A Geological Miscellany. Compiled by G.Y. Craig and E. Jean Jones. Pp.216. ISBN 0-946193-00-2. (Orbital Press, PO Box 141, Oxford: 1982.) £8.95.

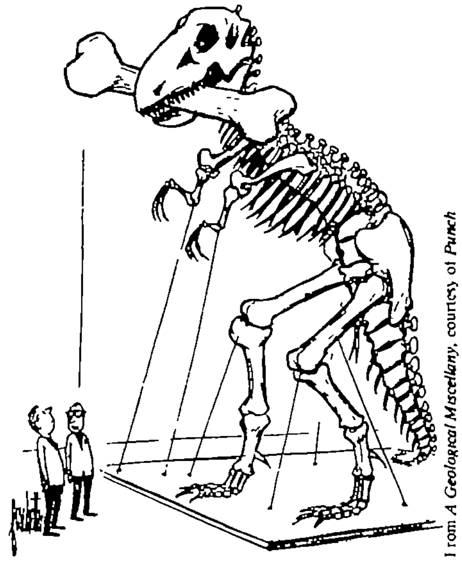
FOR many years it was the pleasant custom of the Geological Society of London to present new Fellows with Woodward's history of the Society's first hundred years. I know of no other book which conveys so effectively the liveliness and fun of those who set geology on its way early last century. Babbage in 1830 wrote of the discussions at the Society that "to say . . . they are very entertaining is the least part of the praise which is due to them".

To my mind Professor Craig and Mrs Jones might have done more to bring out the ability of so many pioneers to do serious work in a light-hearted and enjoyable way, and to convey the excitement of a youthful science. True, they have collected some nuggets, but the grade of the ore they have worked varies greatly and some of the longer of the 130 or so passages in this miscellany might have been consigned to the tip heap in favour of better material.

The two editors nevertheless should be congratulated on their happy thought of bringing together "a pot pourri of adventure, anecdote, epigram, autobiography, discovery, hypothesis and bureaucratic absurdity". There is plenty of material available, for geologists are gregarious people who pass on good tales from one generation to the next: it is still possible to encounter Fellows of the Geological Society who remember Archibald Geikie, who had been out in the field with a geologist who in turn had been on a geological excursion with James Hutton, born in 1726.

Craig and Jones have cast widely over the English-speaking world from New Zealand to New England and even beyond to Pliny on the destruction of Pompeii.

Among the treasures they have come up with are verses by J. Maynard Smith on the "Danger of Being too Clever" (part of a collection presented to J.B.S. Haldane) and a poem by Edward Forbes addressed to a lady whom he must subsequently have left for another. We encounter Edgeworth David suspended over an Antarctic crevasse yet too polite to disturb his only companion, Mawson, who was changing photographic plates unaware of Edgeworth David's predicament. We hear of Ami Boué declining an offer of six Bulgarian maidens when in the field early last century, and of Mary Anning's exchanges with the King of Saxony. Mention of royalty brings to mind one of the best geological passages, an account by Queen Victoria of the parallel roads of Glen Roy.



From A Geological Miscellany, courtesy of Punch

"It seemed logical. We had one bone left over."

These are good historical vignettes; and there is genuine scientific interest in a letter from Sedgwick to Darwin expressing his reservations on the *Origin of Species*, and in an equally sceptical reaction from a Geological Society of America audience to Griggs's paper on convection currents in the mantle. More as good as these would have been preferable to the accounts of swindlers in nineteenth-century USA, of an alcoholic drive through New Mexico and of diamond hoaxes in England which together take up a tenth of the book. And it was insensitive to guy Edward Greenly's tribute to his wife.

All in all, my verdict is — a good idea, could have been carried out more effectively. Let Johnson (quoted p.161) have the last word. Boswell: "Is not the Giants' Causeway worth seeing?". Johnson: "Worth seeing? Yes, but not worth going to see". That sums up the book. ☐

John Sutton is Pro Rector and Professor of Geology at Imperial College, University of London.

More of dinosaur extinction, and more

Malcolm C. McKenna

Hunting the Past: Fossils, Rocks, Tracks and Trails — The Search for the Origin of Life. By L.B. Halstead. Pp.208. ISBN 0-241-10899-3. (Hamish Hamilton/Doubleday: 1982.) £10.95, $19.95.

Beverly Halstead is probably most familiar to readers of *Nature* as the instigator of various criticisms of scientific work at the British Museum (Natural History) and of its epistemologically exciting exhibition policies. Polemics apart, he has also published some very important research on Palaeozoic fishes and on vertebrate hard tissues.

In *Hunting the Past* he shows us some of the wonders of geology, palaeontology and physical anthropology, explained simply and with apt and captivating illustrations, most of which are in colour. The book is aimed at beginners but focuses more on geology and on the romance and history of fossil hunting than on how scientific studies are conducted once the field-work stage is finished. *Hunting the Past* is in the *Time–Life* tradition, a book for the intelligent layman but not for the edification of advanced amateurs or professionals.

Much emphasis is given to the ever-popular dinosaurs. The sections on speed and body temperature are welcome improvements over most of the older popular treatments, in view of the obvious complexity of the subject and Halstead's need to simplify in the space available. At several places in the book, however, the reptile-like mammals (therapsids) are dubbed paramammals, an unnecessary redundancy. One wonders why the dinosaurs were not dubbed parabirds!

On the subject of dinosaur extinction, Halstead discounts the currently fashionable asteroid impact hypothesis, noting correctly that many dinosaurs were already extinct by the time of the Cretaceous–Tertiary impact event and its associated iridium anomaly and disruption of the calcareous marine biosphere. No one doubts that crashing asteroids would have had no effect on already extinct organisms, but the argument that the extinction of the very last of the dinosaurs is close enough to the K–T boundary to coincide with it is now being championed with renewed statistical evidence by Louis Alvarez.

Further, anti-asteroid arguments that dinosaur extinction was diachronous from north to south rest heavily on palaeomagnetic polarity stratigraphy that is itself suspect. Anomalies may be missing from the stratigraphic record of the San Juan Basin of New Mexico because of a mistaken lack of notice given to a late Cretaceous to early Palaeocene unconformity beneath the restricted Ojo Alamo Member of the Nacimiento Formation. Moreover, Archibald recently reported a lignite ("Will the Real Z Coal Stand Up") beneath the famous Bug Creek Anthills site in Montana. There are even rumblings that dinosaurs have been found above what is identified as the Z coal elsewhere. The fat is likely to remain in the fire for some time while all this confusion is sorted out. Meanwhile, Halstead is unwise to play down the asteroid impact hypothesis as a cause of extinction of the last of the parabirds.

In the anthropological part of the book the Piltdown Hoax caught my eye. Even the Loch Ness Monster and Glen Rose Cretaceous "human" footprints from Texas get space. And of course there are some amusing errors and misprints, such as Powell supposedly discovering the Grand Canyon, the multituberculates being categorized as rodents or the apt description of Glen Rose footprint modifiers as "Cretationists".

At the end of the book there is a section on classification in which, true to form, Halstead misinterprets cladistics. He seems to have read Hennig's 1966 book, but the subject has progressed a bit since then. In all, Halstead's attempt to purvey palaeontology and geology to a non-professional audience is a creditable effort — but it falls far short of excellence. ☐

Malcolm C. McKenna is in the Department of Vertebrate Paleontology at the American Museum of Natural History, New York.

Going to ruins in central America

Warwick Bray

The Complete Visitor's Guide to Mesoamerican Ruins. By Joyce Kelly. Pp.527. ISBN 0-8061-1566-1. (University of Oklahoma Press: 1982.) $35.

There have been, as the saying goes, plenty of guide books to Mesoamerican ruins, but never one like this. The author covers 119 archaeological sites (graded from one to four stars, in terms of viewability) and also 41 museums in Mexico, Guatemala, Belize, Honduras and El Salvador. A "Complete Guide" it is not, and every reviewer will lament different omissions (I particularly regret the Cacaxtla murals and the new excavations at the Aztec Templo Mayor in Mexico City), but all the principal sites are included, as well as an enterprising selection of second quality sites in the Maya zone and Pacific Guatemala.

Information on the cultural background to the architecture is rather sketchy, and technical terms are occasionally used without explanation. On the credit side, the book is lavishly illustrated with photographs, but would benefit from more detailed site maps, and has only a short and selective bibliography at the end. For each individual site the author includes a section (sometimes quite lengthy) on the history of discovery and research, giving the names of the excavators, with their institutional affiliations and the dates of their investigations, but not the full bibliographical references that would carry the serious amateur forward to the next level of reading. This merely causes frustration, and was a serious error of judgement on the part of the author or publisher.

The introductory chapter contains much good general advice, on everything from camera equipment to car insurance, but is strongly slanted towards the North American reader. British tourists should check their own visa requirements and, with the collapse of the Mexican peso, should watch out for changes in currency regulations. Probably, too, El Salvador is a place to keep away from at the moment.

The emphasis throughout this book is on how to get to the sites and what to see there. The "ruin buff" (a favourite phrase of the author) to whom this advice is directed comes over as rather timid and of a certain age, driving his — or more probably, her — own car, worried about snakes, insects, sunburn and where to find the nearest cold drink, and in a perpetual dither about whether to wear boots or tennis shoes. Carrying a book of this size, too big and heavy to fit the pocket, walking is going to be hard work. Eye make-up tends to run, but if it rains you can always "carry a wig to wear when you get back to the cities or until you can get to a beauty shop". The main purpose of the visit is not to study aboriginal culture, but to get the best possible photos (or, at least, the same ones that everybody else takes) in the shortest possible time.

It's easy to poke fun, but this is a perfectly legitimate market to aim at. As a visit to any major ruin will demonstrate, there are a lot of people just like this (so many that they tend to get in the way of each others' photos), and they very often need precisely the kind of help that Joyce Kelly's book provides. So, too, do the more snobbish, those of us who through professional arrogance or sheer carelessness have got lost, gone hungry or arrived at a site to find the main buildings in deepest shadow. Thanks to Mrs Kelly, we should not make those mistakes again.

Warwick Bray is Reader in Latin American Archaeology at the Institute of Archaeology, University of London.

Review supplements for 1983

Dates of the five special review issues to be published by *Nature* in 1983 are: Textbooks, March 10th; Spring Books, April 28th; Journals, October 6th; Autumn Books, November 10th; and Christmas Books, December 1st.

Wiggles put straight

Peter J. Smith

Inside the Earth: Evidence from Earthquakes. By Bruce A. Bolt. Pp.191. Hbk ISBN 0-7167-1359-4; pbk ISBN 0-7167-1360-8. (W.H. Freeman: 1982.) Hbk $22.50, £17.80; pbk $11.95,£9.95.

PROFESSOR Bolt has dedicated his latest book not only to the pioneers of seismology in general but to Richard Dixon Oldham in particular, and with good reason. Though little remembered these days, it was Oldham who first showed, in 1906, that earthquake waves could be used to demonstrate the existence in the Earth of major physical discontinuities and thus of a large distinct central core. Indeed, the reading of Oldham's paper on the subject to the Geological Society was a far more significant event for the Earth sciences than the now better-known San Francisco earthquake that was to follow just a few weeks later, for although the disaster in California undoubtedly gave both a scientific and a political boost to the study of seismology, it was Oldham who enabled such study at last to be "removed from the realm of speculation into that of knowledge".

The particular dedication is also appropriate in a quite different sense, even if Professor Bolt would not say so himself. Oldham's 1906 paper was a model of exposition; and in his own way and with far less tractable material Professor Bolt hardly achieves less. There are, for example, few things in seismology more difficult to explain to the non-specialist or undergraduate than terrestrial spectroscopy and few things more mind-boggling than trying to envisage the overtones of the spheroidal and toroidal eigenvibrations of the Earth. After reading Professor Bolt's 18-page chapter on these free oscillations, many may well feel that some of the minor mathematical and notational details elude them; but they will hardly come away with less than a very firm grasp of the physical principles involved. To be able to impart a strong sense of what is actually going on, as opposed to merely presenting some obscure mathematical description, is no mean achievement.

On the principle that anyone who can successfully explain the nature of the Earth's free oscillations can explain anything, it comes as no surprise to find that Professor Bolt maintains the same high standard of exposition in dealing with the rather less exotic, but no less interesting, aspects of seismology — the nature and measurement of earthquake waves, the significance of wave paths and travel times, the interpretation of seismograms in terms of broad Earth (and lunar and Martian) structure, the elucidation of finer (transition zone) structure, the estimation of density from seismic properties and so on.

An innovative approach to animal behaviour

NEW

Functional Ontogeny Explorations in the Functional Analysis of Behaviour
Edited by
David McFarland
Leading experts in the field of animal behaviour are concerned with developing a theoretical framework for a functional approach to the study of ontogeny.
Taking as a starting point the basic concepts in quantitative ethology, this book explores topics relevant to ontogeny. In particular, life history strategies and functional aspects of learning are discussed.
Contributors: Freeman, Houston, Kacelnik, McFarland, McNamara, Tovish.
1982/204 pages/Paperback
ISBN 0 273 08545 X/**£8.50**

Other recent titles from our Bioscience Programme include:

Molecular Approaches to Evolution
Jacques Ninio
This book explains aspects of molecular processes that are used by the cell in order to evolve. It provides a highly readable reflection on the genetic code and its origins.
1982/140 pages/Paperback
ISBN 0 273 08521 2/**£5.95**

Competition and Coexistence of Species
A J Pontin
Competition and coexistence is a developing subject which has been inadequately covered in textbooks. This thorough review emphasises the experimental evidence for populations interacting in the field, and includes critical discussion of theoretical concepts.
1982/112 pages/Hardback
ISBN 0 273 08489 5/**£8.95**

Pitman Books

Circle No.29 on Reader Service Card.

The result is a brilliant non-specialist introduction to the ways in which "the wiggles carry news about the deep interior of the Earth". It can be used as an elementary text in seismology, as a primer for non-seismological Earth scientists or by the layman who seeks a lucid account of the subject; for each of these audiences, not the least of its strengths is that it takes trouble to explain those fundamental principles and ideas (for example, the nature of direct and inverse problems) that so many authors of even basic texts mistakenly take for granted. □

Peter J. Smith is Reader in the Department of Earth Sciences at the Open University, Milton Keynes, and editor of Open Earth.

Carbon dioxide and climate (and journalism)

John S. Perry

Future Weather and the Greenhouse Effect. By John Gribbin. Pp.302. ISBN 0-440-02498-6. (Delacorte Press/Eleanor Friede: 1982.) $15.95.

JOHN GRIBBIN essays a formidable task: to explain the genesis, mechanisms, history and probable future course of Earth's climate in some 300 pages of non-technical prose. His presentation is admirable in its design and broad thrust, but he has left some nasty booby traps for the unwary reader.

Over the lifetime of our planet, atmosphere, climate and life have evolved together. Climate has varied throughout the long history of the globe, and the short history of man. Rapid changes in climate could have drastic consequences and are a legitimate cause for concern in a world already uncomfortably dependent on crops from a few climatically favoured lands. The most important human influence on climate is likely to be an increase in atmospheric carbon dioxide from the combustion of fossil fuels; models of the Earth's atmospheric and oceanic systems project significant changes in the workings of the great heat engine that powers our winds and governs our climate. Future weather will be different, and mostly warmer.

However carbon dioxide "feeds" plants, farmers are clever and people will probably continue to starve or grow fat primarily because of society's aberrations, not those of the weather. Changing climate — whatever its origin — simply complicates our task of providing energy, food and a decent life for everyone on Earth.

Communication of this thread of understanding to the public would be a noble achievement. Indeed, Gribbin's attempt has certain points to recommend it. He wields a breezy, conversational style and has a journalist's eye for arresting details of personality and event. Moreover, his explanations of certain scientific concepts and research results are outstandingly clear and accurate. For example, his discussion of the greenhouse effect is a model of its kind, and the core of his outline of the general circulation is probably as good as can be achieved without recourse to mathematics.

Unfortunately, other flaws sadly vitiate the book's value and betray its promise. The introductory chapters are crammed with a motley assortment of climatic titillations — droughts and blizzards and ice ages — each hurriedly and simplistically linked to one or another meteorological abstraction. Jet streams, the circumpolar vortex and the Intertropical Convergence really make sense only in the context of the general circulation, an insight postponed until Chapter 3. By that point, the lay reader may find himself mixed up and turned off.

The major failing seems to stem from a mismatch between the nature of science and the demands of journalism. There is a popular misconception that scientists are people who look for answers. That's nonsense, of course: although they generally share a working consensus, scientists are at root people who like to ask questions and pose hypotheses. Bearers of all sorts of ideas are eagerly welcomed to science's great and never-ending party, and the climate corner of the affair — one pictures it as lying between the hors d'oeuvres and the bar — is particularly crowded.

Thus, climate vies with politics, economics and religion in the number and variety of theories per unit of fact. All attempt to explain some aspect of the behaviour of a complex and poorly observed heat engine employing turbulent working fluids, subject to changing forcing, and tampered with to an unknown extent. Variability on all time-scales is a natural and inherent characteristic of climate, so it is no wonder that plausible connections can be adduced between almost any hypothesized cause and virtually any climatic consequence. Few survive independent data and scrutiny, yet Gribbin appears ready to embrace almost any theory — one longs to sell him a used car. The Sun–weather relationships, for instance, to which many pages are devoted, have proven particularly fragile, and it is misleading to treat these empirical speculations as established facts. Physics should rule over statistics, and a treatise on climate should seek to present a sound consensus and be built upon critical scientific judgement.

Instead, the book seems to have been constructed with the help of a vacuum cleaner and a glue pot. One imagines the author pointing his nozzle into all the dusty corners of the village library and cheerfully pasting up with unbounded enthusiasm whatever comes down the pipe — trash and treasure alike. One scientist's solar-based forecasts have "invariably proved right", a judgement shared by few and contradicted a page later. The atomic bomb and man-made aerosols are brandished as precursors of an ice age. For some reason, one dubious claim of geomagnetic-climatic connections merits an entire chapter, while another naive misinterpretation of irrelevant observations "commands respect" in assessing CO_2-induced climate changes. It is astonishing that Gribbin, a physicist by trade, swallows an outrageous claim that even an atmosphere totally opaque to thermal radiation could warm the surface by no more than 4°C. Physics aside, hasn't he ever heard of the heat wave on Venus?

Future Weather and the Greenhouse Effect has many ingredients of a badly needed commodity — a well-balanced and comprehensive book on climate for the layman. The man in the street, however, would be best advised to look elsewhere for a balanced understanding of knowledge and speculation is this important and exciting area of science. □

John S. Perry is Executive Secretary to the Board on Atmospheric Sciences and Climate, National Academy of Sciences, Washington DC.

NEURO-TRANSMITTER AGONISTS FROM BIOSEARCH

BIOSEARCH offers a number of unique neurotransmitter agonists of recognized value. All are natural products isolated in our laboratories and are of exceeding purity.

QUISQUALIC ACID

A universe without mathematics

Hermann Bondi

The Lighter Side of Gravity. By Jayant V. Narlikar. Pp.194. Hbk ISBN 0-7167-1343-8; pbk ISBN 0-7167-1344-6. (W.H. Freeman: 1982.) Hbk $17.95, £13.95; pbk $9.95, £6.95.

JAYANT Narlikar's *The Lighter Side of Gravity* is a splendid effort to bring together many of the most exciting facets of physics and astronomy in a logical argumentation devoid of mathematics. Much so-called popular writing on physical science is content with a description of where today's science has got to; moreover, such a description is often marred (particularly in the media) either by delighting in stressing how "crazy and incredible" it all is, or by regarding the development of science as a sort of intellectual stock exchange where individual scientist's stock rises and falls according to how "right" or "wrong" their views have turned out to be (as though a scientist's standing depended on this!).

Narlikar is wholly free from these faults. He respects his reader and takes him gently, almost imperceptibly, through many of the important arguments leading to the advanced concepts of black holes, of the source of stellar energy, of white holes and of the structure of the Universe. He is outstandingly successful in this, though I feel that some of his derivations are a trace old-fashioned in their nature and in the analogies used. His clear writing, stressing how intelligible it all is, is a delight and indeed a breath of fresh air in contrast to so much of the sensation-hungry writing in this field.

There can be no doubt that this book meets an important need and meets it very well indeed. Yet one must admit that it is a curious aberration of our educational system that the need for such a book without mathematics is so great. Mathematics is used in physics and in astronomy to make arguments easier, to make the work lighter. Yet we create such a phobia of equations and formulae in the bulk of the population that there is a continuing demand for books that try to make the going easier by explicitly *excluding* mathematics. This is no fault of the author or of this splendid book, but rather a fault of us all for engendering in so many thinking people a violent reflex action to anything mathematical. ☐

Sir Hermann Bondi is Chairman of the Natural Environment Research Council. His books include The Universe at Large *(Heinemann, 1961) and* Assumptions and Myth in Physical Theory *(Cambridge University Press, 1967).*

Sky-watchers A to Z

Stephen P. Maran

Observatories of the World. By Siegfried Marx and Werner Pfau. Pp.200. ISBN 0-7137-1191-4. (Blandford/Van Nostrand Reinhold: 1982.) £8.95, $16.95.

IN *Observatories of the World* two astronomers at the University of Jena tell tales of 40 of their favourite observatories from Abustumani to Zelenchukskaya. The observatories have been selected to represent institutions of different types, including those that are research-orientated and education-orientated, those with optical, radio and infrared intruments or specializing in elaborate computational tasks, and those located in cities, on mountaintops or (in one case) aboard an aircraft. The English-language translation is by Simon Mitton, who also revised the text.

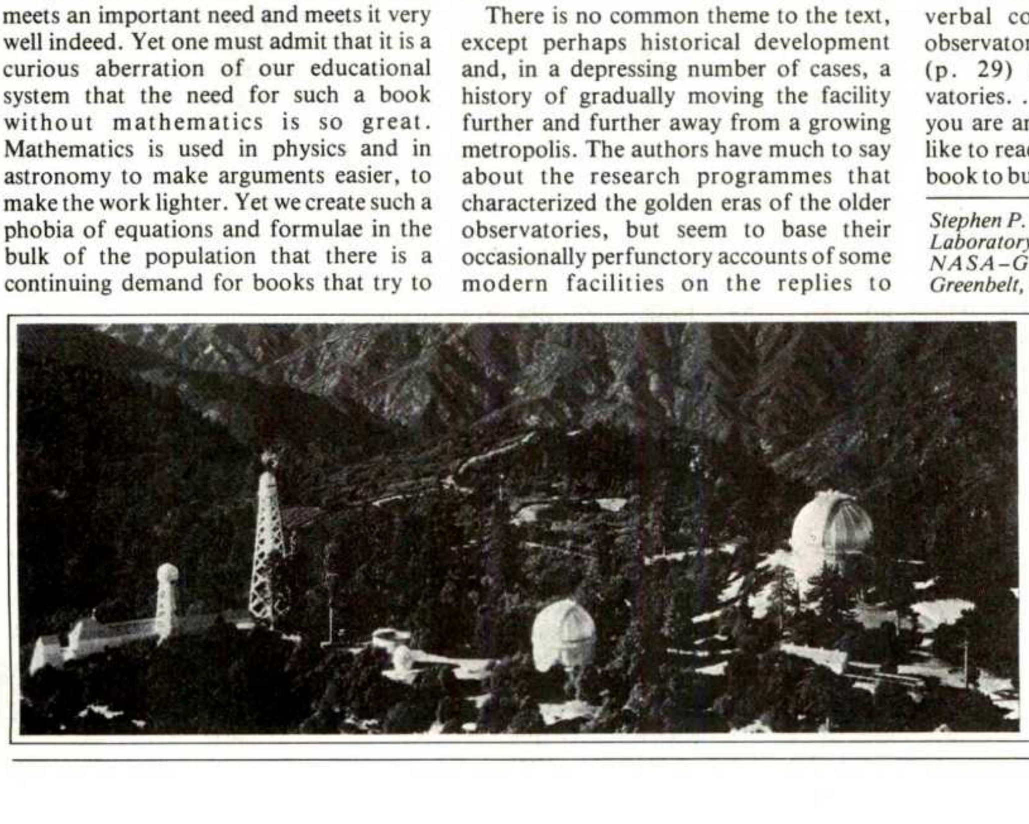
There is no common theme to the text, except perhaps historical development and, in a depressing number of cases, a history of gradually moving the facility further and further away from a growing metropolis. The authors have much to say about the research programmes that characterized the golden eras of the older observatories, but seem to base their occasionally perfunctory accounts of some modern facilities on the replies to questionnaires that were distributed to the observatory authorities. This is not a professional reference work, then, nor a directory; there are no tabulations of telescopes and instruments, nor of observatory coordinates and altitudes.

Not all of the facilities described would have made my "Top 40"; the omission of Yerkes Observatory (mentioned in passing, and incorrectly, as being located "in the East of the United States") is particularly unfortunate for it was at Yerkes that much of modern astrophysics was born. Cerro Tololo Inter-American Observatory, that great and much-used telescope farm in Chile, is also not included, although it is briefly described in the section on its sister facility at Kitt Peak.

Observatories of the World is written for those who have some familiarity with the terminology of astronomy, although a number of elementary concepts are explained. It is extensively illustrated with attractive half-tones and rather primitive sketches (plates 11 and 12 appear to be interchanged, incidentally, but most readers should be able to tell a coronagraph from another kind of telescope). Only here, among books that come conveniently to mind, can one readily determine that the ancillary building of Konkoly Observatory near Budapest "has a grass-covered roof and cannot therefore be a source of troublesome air turbulence. . ." or that the little town of Coonabarabran provides scientists with "all the comforts of civilization". Amidst the interesting trivia, however, there is a brief but frank discussion of optical problems with the original 6-metre primary of the huge reflector at Zelenchukskaya, and many other informative titbits.

The overall result is a pleasant and informative book, despite some awkward verbal constructions such as "Every observatory not recently established. . ." (p. 29) where "The older observatories. . ." might have done as well. If you are an armchair astronomer and you like to read about observatories, this is the book to buy. ☐

Stephen P. Maran is Senior Staff Scientist in the Laboratory for Astronomy and Solar Physics at NASA–Goddard Space Flight Center, Greenbelt, Maryland.



Mount Wilson Observatory in southern California. To the left are three solar telescopes, centre and right are the domes of the reflectors. The picture is taken from Richard Learner's *Astronomy through the Telescope,* recently published by Evans/Van Nostrand Reinhold. Prices are £12.50, $29.95. The excellent illustrations and accessible but comprehensive text make the book a stimulating guide to the history of astronomy and its instruments for both professional astronomer and layman.

The cosmos and its contents

David W. Hughes

NEW BOOKS on astronomy continue to flood on to the market, the fact that we are not swamped by them being due to their short life; few last more than two years before going out of print or finding their way onto the remainder shelves. The astronomical second edition is indeed a rarity. Nineteen eighty-two, however, does have advantage over other years — it is the twenty-fifth anniversary of the start of the space race. My first book deals with just that.

Sputnik to Space Shuttle by Iain Nicolson (Sidgwick and Jackson, £7.95) chronicles the childhood of the space age. We start with the characteristic "bleep bleep" of the Soviet Union's Sputnik 1 which astonished the world on 4 October 1957 and end with the graceful landing of Columbia which completed the fourth test of the Space Shuttle in June of this year. Between these dates there is all the excitement of the race into space, the Soviet Union and the United States continually jockeying for the lead. First dog in space, man in space, woman in space and space walk went to the USSR; first voice from space, navigation satellite, meteorological satellite and communications satellite went to the USA; first photographs of the far side of the Moon, first lunar soft-landing, first Venus soft-landing to the USSR; first men on the Moon, first two-planet mission, first Mars lander to the USA. One could continue but why not just read Nicolson's book. He is a lively writer with a clear, easily readable style and his book is an excellent review of our 25 years "out there".

For a more scientific bias we have **Planets of Rock and Ice** by Clark R. Chapman (Charles Scribner's Sons, $13.95), a revised and expanded edition of his 1977 book *The Inner Planets*. The author folds together our knowledge of terrestrial planets with the new-found information gleaned from the space probe observations of the satellites and rings of Saturn and Jupiter. This book is raised above the mundane plane of the usual account of the planets by the many anecdotal insights into the workings of the mind of a planetologist that grace its pages. Chapman loves his job, loves the planets and it shows.

In the book he inveighs against the shut down of Solar System explorations that has been inflicted on the American scientific community. There is, however, a very minor advantage to this in that scientists will no longer be distracted by the "gee whiz" findings of new planetary encounters or the need to plan for forthcoming missions. So the storerooms of accumulated information, the thousands of pictures and unprocessed magnetic reels of data, now have a chance of being sifted and scrutinized. Be this as it may, there are still a multitude of places to go to and experiments that cry out to be performed.

The evolution of Earth's surface and atmosphere and the way it contrasts with its rocky neighbours is obviously of great interest and concern to Chapman. His ability to express this vividly makes the book a joy to read. But how different is the state of planetology today in comparison to the time when Apollo 11 landed. The London bookmakers William Hill were then offering odds of 100:1 against a manned Mars landing before 20 July 1976 and "evens" on a landing before 20 July 1979!

The Planet Venus by Garry E. Hunt and Patrick Moore (Faber & Faber/Faber Inc.; £10, $22) divides neatly into two parts. Venus before the space age is mainly written by Patrick Moore and concentrates on the way Earth-based telescopic and spectrographic observations moulded our pre-1962 view of the planet. Transits, the Black Drop problem and the ashen light are carefully reviewed, as are more marginal and esoteric phenomena such as the debate that took place in the 1950s as to whether the surface was covered with oil, water or dust, the aphroditographic work of Percival Lowell that "revealed" a series of dark patches and strips on the planet and a rotation period synchronous with the orbital period, the discovery of a phantom satellite and its subsequent demise, and the early attempts at measuring the surface temperature.

Venus made its entry into our space age in December 1962 when Mariner 2 flew by, and the voyages of discovery have continued with a whole series of Venera, Mariner and Pioneer spacecraft. Garry Hunt reviews the latest ideas about Cytherean greenhouse effects, atmospheric sulphur cycles, wind profiles, circulation patterns, and day and night variations. Pictures are shown of the surface of Venus near the Venera 9, 10 and 13 spacecraft, and the results of the radar observations of the landscape using data from the Pioneer orbiter and the Arecibo and Goldstone radar facilities are reviewed.

Venus is often regarded as the Earth's twin but an identical twin it certainly is not. This book is a very good account of our knowledge of our nearest planetary neighbour; I was especially impressed by the extensive reference section which will encourage readers to delve further.

Now for something completely different. What started in the United Kingdom in 1767 and the United States in 1855? It was the forerunners of the **Astronomical Almanac** and the 1983 version (US Government Printing Office/HMSO; $16, £9.25) would make an excellent gift for the astronomer who has nearly everything. Where else would you easily find the universal times of the greatest northern elongation of the satellite of Pluto close by lists of the 194 brightest galaxies (together with diameters, photometric data and velocities), the 1,482 stars brighter than 4.5^m, the latitude and longitude of the world's optical observatories, the circumstances of all the 1983 eclipses, together with a host of all the usual things we refer to the almanac for? Many happy hours can be spent dipping into this book.

To move closer to the stars, **The Astronomy Handbook** by James Muirden (Kingfisher/Archon; £3.95, $8.95) is a colourful, profusely illustrated guide to the constellations, Sun and Solar System. It is aimed at the teenage astronomer. Muirden concentrates on the practical side of the subject and I really like his plan for a do-it-yourself planetarium — no young astronomer's bedroom should be without one. The book is full of encouragement, more than enough to make any youngster grab a pair of binoculars, brave the cold of a starry night and take to examining the heavens.

Planets first, stars next and finally the Universe and all the theories and phenomena of the cosmos. **Deep Space** by Colin Ronan (Macmillan, London/Macmillan, New York; £10.95, $25.95) and **The Restless Universe** by Nigel Henbest and Heather Couper (George Philip, £8.95) both throw their net wide and try and sweep in the whole zoo of astronomical objects from pulsars, quasars and black holes down to stars and planets. Both delve into the mysteries of the big bang, the search for alien life, how it will end (the big crunch?), and the birth and death of stars. It is the differences between the two books that are really startling. Ronan's book is a visual treat and is profusely illustrated not only with photographs of celestial objects but also with a host of well-conceived figures: for example, one diagram shows the relative positions of the brightest members of the Local Group of galaxies and with the accompanying table can form the basis of a model; another does the same for the Sun's nearest 24 stellar neighbours. It is very hard to resist making these models. I gave in straightaway and had great fun. Time and again the illustrations really punch home the message of the text. The figures are exciting, the text interesting and I have no hesitation in recommending Ronan's book.

Henbest and Couper confine themselves to 24 figures and 24 colour photographs and I feel that the authors have set themselves the age-old problem of describing a spiral staircase with their hands in their pockets. This comment apart it must be admitted that the text rattles along at a heady pace — nobody will fall asleep reading this book. ☐

Human guinea pigs have a choice

The British Medical Research Council is to carry out a five-year, controlled trial of vitamin supplements in the prevention of neural tube defects. But it should still adopt more open discussion of the trial.

Should people ever be used as guinea pigs in the investigation of a new drug or some new medical treatment? That is one of the questions on which opposition has been focused in the past few months to the proposed British trials of the efficacy of vitamin supplements, including folic acid, as a means of preventing neural tube defects (including spina bifida) in human births. The simple answer to what is an over-simple question is yes. People should be used as if they were experimental animals in proving new medical treatments. Moreover, people are already being used widely for just that purpose. But the analogy with guinea pigs is false. Guinea pigs are not able to choose whether to be part of some controlled trial in the laboratory. People invited to help test some novel treatment are, on the other hand, first given an explanation of what is intended and then an opportunity to decide whether or not they will participate. This is why it is right, if nevertheless courageous, that the Medical Research Council should have decided to go ahead with its long-planned trial of vitamin preparations as a means of preventing the recurrence of spina bifida births.

The planned trials are nevertheless unusual for several reasons. The incentive is the appearance in the past few years of evidence to suggest that supplements of vitamins, including folic acid during the first third of pregnancy, will help to prevent the recurrence of neural tube defects. The evidence (see *Nature* 2 December, p.396) is impressive but not conclusive. The planned trial is therefore based on the choice of four groups of women, each of whom has already given birth to a defective child, to which would be administered four different treatments — folic acid alone, folic acid plus more familiar vitamins, vitamins without folic acid and, for the remaining group, a placebo devoid of vitamins. The objective, of course, is not merely to discover whether one of these treatments will reduce the recurrence of neural tube defects but also to find some way of avoiding these defects among all women embarking on pregnancy. The controversy about the trial centres on the presence of the placebo group. Why, the critics ask, deprive one quarter of the women in the trial of any treatment when there is all this evidence that something in the original vitamin cocktail has some effect?

The assumption underlying this question is unfortunately just that. The control groups in the previous studies have not been control groups at all, but merely groups of women who have already had one defective child and who might have been offered vitamin supplements if they had not become ineligible, usually by already being pregnant (and only occasionally by refusal). That there may be some kind of self-selection in the assignment of women to the two groups is clear, although it is unlikely to have been significant. But certainly the women not given vitamin supplements in previous surveys, as in that now being carried out in the Republic of Ireland, are denied the benefits of the well-known Hawthorne effect, the improvement of virtually any social condition that comes about when something new is offered by experimentalists. Consequently, a trial without a placebo group would literally be incapable of yielding results bearing on the benefits that would obtain from the widespread administration of vitamin supplements to all women at risk of pregnancy, not merely those unfortunate enough to have produced an afflicted child. The point is especially important because there appears to be very little direct evidence of the untoward effects that there may be of chronic administration of folic acid, and because it may in the end be necessary to administer whatever vitamin supplement is necessary by adding it to some general component of the diet, bread perhaps. Will those who now complain that a placebo group would be unethical in the forthcoming trial then take to the hustings to protest that it is unethical to add an untested material to everybody's diet?

So the case for going ahead with the Medical Research Council's trial is strong. The obvious alternative approach, the detailed investigation of the concentrations of various vitamins in different kinds of body cells at different times of life, but especially in pregnancy, would no doubt be valuable (and should not even now be neglected). The case for an independent investigation of the effects of the chronic administration of folic acid in laboratory animals is strong, but as a necessary complement to the trials now planned. But none of this could possibly yield, in the near future, guidance on what should wisely be done to reduce the incidence of neural tube defects in the population as a whole. Only the trial can do that.

But will the Medical Research Council be able to recruit the physicians and their patients whose cooperation will be necessary after all the controversy there has been? The council's statement last week says that it is anxious on this point. The burden of advising women whether to take part in the trials will after all fall on family physicians, not on the research council's officials. One particular difficulty will be that women who are unable to accept that a fetus diagnosed as carrying a neural tube defect could be aborted will be reluctant to take part. For others, the crucial consideration will be whether the proposed trials will be accompanied by thoroughly reliable means of diagnosing neural tube defects early in pregnancy. The Medical Research Council should not be afraid that the provision of such arrangements will expose it to the scurrilous charge that it is prepared to offer abortions to women taking part in the trial. In these circumstances, as in the ordinary ups and downs of pregnancy, such questions are questions between women and their physicians.

None of this implies that the Medical Research Council will have an easy passage in the five years ahead. While the council has been attacked unfairly on many occasions in the past few months, it should itself acknowledge that it has helped to exaggerate its own difficulties by its attempts to control open discussion of its plans. The pantomimic suppression of two letters from *Nature* correspondents a few weeks ago (see 25 November, p.310) was thoroughly unreasonable; it was probably, in the event, counterproductive. In the coming months, the council should resolve to be more open about its plans. For example, the protocols that have no doubt been drawn up to help decide when the trial should be abandoned, perhaps because significant evidence has accumulated in one direction or the other, should be openly published. Tactically, and so as not to compromise its other good works, the council should remind anyone who will listen that it is not the prime mover behind the spina bifida trials but rather the agent of the Department of Health, which originally set the ball rolling. But, for the long term, the council should also insist not merely on the need for this planned trial but also on the fact that advanced communities such as the British cannot look for all the benefits of modern medicine if they shy away from the need for trials in which some people are put at risk.

Ocean bed law disaccord

Several countries have not signed the Law of the Sea. A compromise must eventually be found.

The conference at Montego Bay in Jamaica to celebrate last week the signing of the Law of the Sea was by all accounts more like a wedding without the groom than a funeral without the corpse. The air of mutual congratulation was real enough. More than a hundred states turned up to sign the treaty; a third as many, including the United States and most of the industrialized states of Western Europe, stayed away. The issue that divides the two groups is now familiar: the arrangements in the treaty as negotiated for the exploitation of minerals on the sea-bed.

The disagreement is partly geographical. Within the newly defined "economic zone" of 200 miles around each maritime state, governments will be free to take what minerals they can find. Beyond that it will be necessary for those with the techniques for extracting minerals from the sea-bed to limit what they take but also to "share" their "technology" with other states that may share ambitions to win minerals from the deep oceans. While the provisions now put forward in the Law of the Sea are a good deal more realistic than those originally canvassed, they still give offence. The essential difficulty is that of making a bridge between the commercial interests of those who may in due course wish to retrieve minerals from depths of several kilometres, and who will presumably have to spend substantial amounts of their own money to reach a position in which they can do something worthwhile, and the objectives of those who are more concerned that the deep sea-bed should become a kind of international heritage of mankind. But too many of the schemes which are compromises between commercial interests and international idealism will work less than efficiently.

Several questions arise, the chief of which is that of who can be blamed for the way in which the Law of the Sea has not been signed by the potentially most important signatories. The impasse that has arisen was apparently well concealed at Montego Bay last week. The temptation now is to blame the United States for what has happened, and indeed the behaviour of the US delegation at the negotiations in New York earlier this year was a shameful mixture of indecisiveness and arrogance. But in reality what the Reagan Administration was saying that it would be a dangerous precedent if they were bound by the terms of an international treaty to share technology on terms unspecified and by means not understood and that the provisions of the Law of the Sea on deep-sea mining are merely a continuation by other means of the longstanding argument between the developing countries and those of the industrialized West. It would have been better for all concerned if these points had been made more openly much earlier in the negotiations.

So what happens next? Technically the treaty will come into force only when sixty of its signatories have taken the formal step of ratification, which is expected to take two years. Then, after a further five years, there will be a review conference at which the working of the treaty will be re-examined, and when it will be possible for those who have ratified the treaty to put forward amendments. Those not (repeat not) present at Montego Bay last week are now saying that they will nevertheless turn up at the review conference, if only as observers, to repair some of the damage that has been done. The snag is that without formal status as members of the treaty, they will be able to put forward new proposals only with the consent of the developing countries to which such offence has now been given.

Meanwhile, the signatories of the treaty are saying that as it now exists it is binding even on those who have chosen not to sign. The case for that position is weak. The signatories at Montego Bay last week may be right in saying that they could take non-signatory violators to the International Court of Justice at The Hague, but there is no reason to think they would win their cases.

So does the future hold merely a kind of licensed piracy on the sea-bed and even on the high seas? Given the likely pace of development of sea-bed mining, mineralogical piracy is unlikely. The provisions on the rights of innocent passage in narrow straits are more immediately important. The danger, in the present stand-off between the signatories and the others, is that their disagreement may become open dispute at times of international tension. Would the rights of passage through the Red Sea of merchant ships from non-signatory states always be assured if there were some future conflict in the Persian Gulf? This is the kind of anxiety that should keep the non-signatory governments awake at night, and on the look-out for a more persuasive compromise than they have found so far.

Unorthodox assessments

A recently published book provides an intriguing glimpse of peer-review in action.

Like restaurant proprietors, journal editors have the right to refuse admission to anyone, the obligation to explain their attitude being merely moral. Dr Stefan Marinov has therefore performed a useful and courageous service by revealing in print* the manner in which journals (including this one) and funding organizations around the world respond to this obligation. For some years, Dr Marinov has submitted papers and proposals concerning "absolute space-time" to such bodies, with — by his own account — a rather small degree of success. Literal copies of this correspondence make up the bulk of his book and are absorbing reading.

It is an inevitable part of the duties of every editor to assess papers that lie near what may be called the fringe of science. Physics journals and "general" journals receive many attempts to "correct" the theory of relativity or to propose new laws underlying the structure and evolution of the Universe. Some papers are based on numeralogical mysticism or are in some other way so speculative and unpredictive as to justify immediate dismissal. Others contain mathematical errors. Some (as in Dr Marinov's case) contain detailed arguments, often including descriptions of experiments, which require more lengthy assessment.

Dr Marinov's book reveals some of his arguments and the reception they received. As a result, it is something of a handbook for editors faced with the need for an appropriate choice of words if the assessment process has revealed that rejection is the appropriate course of action. Does one follow, at one extreme, the rather curt approach of *Science* ("We decline to publish your paper on 'Measurement of the one-way velocity of light and the Earth's absolute velocity'. The manuscript is enclosed.") or, at the other, does one follow the editor of *Zeitschrift für Naturforschung* and (as Dr Marinov relates) exchange more than twenty letters and give the author an explanatory conversation over a pizza? Between these two lie the responses of some 35 other journals and the National Science Foundation (four referee reports followed by formal appeals up successive rungs of the hierarchy).

What can or should be learned from such a book? Those as tenacious and as radical in their scientific approach as Dr Marinov will learn what to expect in tone and quality from the variety of journals available to them. Those responsible for journals or funding bodies will gain a glimpse normally denied them of their colleagues in action. They may be drawn to conclude that to refuse publication without providing justification is to do less than justice to any author and plays into the hands of conspiracy theorists. They will note with disquiet that the more conscientious they are in this respect, the more conscientious a reply they will probably receive.

Publishers might conclude that there is a market for an unrefereed journal of unorthodox science. All readers should note how, in this case at least, the system seems to have ensured that orthodoxy prevails — deciding for themselves whether by malevolent conspiracy, inertia or good sense.

Science to rescue EEC politics?

Davignon tackles the agricultural policy problem

Brussels

Scientific research in Europe seems poised to play a most unaccustomed role: as a tool in a major political issue, one which threatens the European Economic Community: the ballooning cost of the Common Agricultural Policy (CAP).

The CAP, designed in part to keep continental farmers on the land, consumes nearly three-quarters of the Community's budget, leads to enormous food surpluses, and threatens — politically — to blow the Community apart. Related policies of farming support in the United States also produce surpluses. Around 100,000 tonnes of butter, for example, are stored in a Kansas mountain; similar amounts cram cold stores in Europe. The consequent dumping of food on world markets is precipitating something approaching a transatlantic food trade war. Meanwhile, much of the world starves for want of rice, not butter or powdered milk, wine or maize.

The scientific initiative, designed to help solve the problems of CAP comes from the Vice President at the European Commission, Viscount Etienne Davignon — for whom everyone appears to jump when he wags a finger — and from his research director-general Professor Paolo Fasella. Between them they appear to be building the conceptual and political basis, both inside and outside the Commission, of a key role for research in agricultural policy, and, for that matter, in public health, which is another major financial headache for European governments.

These initiatives, still at an early stage (they are yet to be formally discussed by the 13 European commissioners), come after Davignon's success with Esprit, the Brussels programme for the information technologies. Davignon, assisted by Fasella's directorate, has steered Esprit through the labyrinth of EEC and national advisory committees, and around potential political opposition, with impressive speed. (The programme should start next year, only a year after conception. By comparison, an earlier and equally ambitious programme for biotechnology took seven years to reach this stage and is only just getting under way.)

The agriculture research proposals are to be based above all on a detailed analysis of the Community's agricultural budget — on what costs most and why. Beyond that, they relate — for the moment — to five central objectives.

The first objective is to reduce production and distribution costs, so that farmers can make their profit and maintain their living standards on a smaller volume of produce; the second, to upgrade the product; the third, to seek alternative uses of land and people; the fourth, to take account of the specific food needs of developing countries — or, more prosaically, the existing and potental world food market. And the fifth objective is to develop non-food products, such as energy and materials, based on agricultural production.

For example, food storage losses are high, but might be reduced by a small amount of research and demonstration. On quality, Europe could aim to make a smaller quantity of a better wine, or to make high-value cheese from milk rather than low-value powder. ("It makes me mad that we distil wine and dry milk", says Fasella.)

On alternatives, farmers could grow new crops, aided by a little research on what would grow where and be profitable. Fasella himself, before he joined the Commission from biotechnological research in Italy, had a hand in a successful project north of Rome. There, farmers agreed to change from the production of price-supported wheat to strawberries and flowers, with the help of a little science and low technology.

And on agricultural industry, Europe could, for example, re-examine the use of wood as a material and chemical feedstock. "Lignin [a major wood-waste] is still too little studied", Fasella says.

Exactly when these and related proposals will bear fruit in the form of research contracts with the Commission is not clear, but the ideas are now roughly at the stage of Esprit a year ago. Britain is pushing hard for reform of CAP. Most nations at least recognize its over-weight, and all might see the emerging research proposals as a useful aid to change — or to defusing a politically dangerous situation. If things moved as fast as Esprit, there could be tenders by 1984.

Besides agriculture, health is also on Commission minds. The cost of the European public health services (111,000 million European units of account a year — £61 million — for the 10 EEC countries except Greece, according to World Health Organization figures) could also be reduced by the right kind of research, Davignon and Fasella are arguing. The bulk of health service costs come in hospitalization, and only 14–15 per cent in drugs. The drug companies have had little motivation to develop preventive therapeutic measures — but the profitability of new drugs is declining rapidly. On both sides, therefore, and in other sectors of the health industry, there is an interest in a new approach. As in the agricultural sector, the Commission should start by an analysis of costs, Davignon and Fasella argue. From that point, financial priorities will determine research and development needs and ultimately new products.

Overly ambitious? "We are not aiming to be an eleventh state [beyond the ten of the EEC]", Fasella insisted last week. Rather, the Commission is determined to act as a strong service — to provide new, realistic means of action for member governments. And for the first time, it seems — if Davignon can convince his fellow commissioners — research and development are going to be serious tools of that action. **Robert Walgate**

Carter appointees leave NSF

Washington

Edward A. Knapp, the new director of the National Science Foundation (NSF), has arranged the departure of the three other past presidential appointees at NSF. The surprise move apparently came at the request of the White House which aims to install its own appointees and replace "holdovers" from the Carter Administration.

Donald N. Langenberg, deputy director of the nation's basic science agency, which is traditionally viewed as nonpolitical, will leave by the end of the year, at the request of Knapp and the White House. Langenberg, who is on leave from the University of Pennsylvania, had been a candidate for the director's job. The sudden departure took even NSF's governing board by surprise.

A second Carter appointee, Eloise E. Clark, deputy director for biological, behavioural and social sciences, has reportedly submitted a letter, stating her intention to resign, also at Knapp's urging.

Francis S. Johnson, deputy director for astronomical, atmospheric, earth and ocean sciences, also plans to go. His three-year leave of absence from the University of Texas at Dallas expires soon anyway.

The departures fuelled rumours that the Reagan Administration is politicizing the NSF. But a source close to the foundation said that "NSF is due for a surprisingly large increase in the fiscal 1984 budget, and Knapp was under pressure to have his own people there" in time for the announcement of the figure in January.

The chairman of the National Science Board, Dr Louis Bramscomb, said he had no information suggesting that the departures imply political influence but, he said, "that could show up if Ed Knapp is not given the independence to pick replacements with the highest professionalism. **Deborah Shapley**

West German nuclear power

Fast breeder escapes veto

A vote in West Germany's federal parliament (*Bundestag*) last week promises to relieve pressures on the CDU/CSU/FDP coalition government by helping to remove the technical problems of atomic energy from political debate.

In last week's vote, the *Bundestag* finally agreed to lift the veto on the commissioning of the 800 MW fast breeder reactor at Kalkar. This veto was imposed in 1978 to prevent opponents in the SPD/FDP government from killing the project completely. A commission was appointed to inquire into the safety of the installation and the majority report, published last September, found that the risks of the sodium-cooled breeder at Kalkar were no greater than those of modern pressurized water reactors. The *Bundestag* thus had little choice but to permit start-up in 1983, although most of the SPD used the pretext of the minority opinion to vote against lifting the veto.

From its beginning in 1971, the entire project has been bedevilled by controversy. Delays over the siting of the reactor at Kalkar were followed by the parliamentary veto. The fast breeder project has also been a catalyst to the rise of the "Green" parties as a political force. Other, technical, problems have arisen over technology licensing and in proving the safety and containment in case of accident. According to the review carried out recently by management consultants A.T. Kearney and Motor Columbus for the Ministry of Research and Technology, mismanagement has also contributed to the increased costs and delays.

The overall result is that the costs for the project have been repeatedly revised upwards at a rate well above that of inflation, and now stand at DM 6,500 million (US $2,700 million), up by DM 1,500 million since 1980. Earlier this year, it looked as if this reactor and the other, high temperature, prototype reactor were running out of money. But the government has now found enough to keep them going for 1983, partly through cutting back other energy projects. As a result, well over 10 per cent of the 1983 research budget will be spent on the two prototype reactors.

Further development will depend on investment by the utility companies, based on the *Lander*. They will judge the reactors on the financial returns and it appears at present that the fast breeder will not be competitive before the end of the century. Thus there is a suspicion that a different standard is being applied to nuclear energy from that for other energy research.

On the other hand, the high temperature reactor may interest a wider spectrum of industry, although the prototype has also been subject to delays and increases in cost.

The main interest in Germany is in the use of high temperature steam for the gasification of lignite and bituminous coal, of which there are extensive reserves. Combined heat and power schemes, already in use in some northern cities with conventional power stations, provide an outlet for waste heat. Finally the reactor might be used to drive thermochemical cycles for splitting water to produce hydrogen. The EEC Commission has made hydrogen a major research subject and several cycles are being studied at the Joint Research Centres and elsewhere.

J.S.Dunnett

European atom treaty

New rules

Brussels

France's agreement with India to supply the Tarapur nuclear power station is being questioned by officials in Brussels. The agreement may be breaking the Euratom Supply Agency's monopoly over the supply of nuclear materials which has existed since the Euratom treaty was signed in 1958. The inquiry could be used as a way of applying pressure on France to agree to a revision of Chapter 6 of the treaty which the European Commission is proposing in order to bring it in line with the changes that have taken place in the nuclear industry since 1958.

The new proposals are the third attempt in eight years to bring the treaty up to date. In the past both France and the United Kingdom have opposed such a move in order to protect their nuclear fuel companies, British Nuclear Fuels Limited at Sellafield (Windscale) and Cogema at Cap de la Hague. The Commission suspects that both these companies have been using their market dominance to maximize profits by rigging prices and imposing unnecessary conditions on their customers in the rest of the European Community. Customers have been persuaded not to hold stocks of reprocessed fuels or to sell them to other users and the Commission feels that it would at once be realistic to abolish the illusion of a Euratom monopoly and to insist on a genuinely free market for the nuclear fuels industry. Otherwise there may be some risk that countries such as Belgium and West Germany may decide to build their own reprocessing plants, which would lead to over-capacity in Europe.

The new rules which the Commission is putting forward would give the European Commission the power to penalize anyone imposing any restrictions on trade in nuclear materials inside the Community. Exports, on the other hand, could be contracted on a bilateral basis provided the Commission can ensure that the contract would not damage the interests of any other EEC country. But a certain solidarity amongst the EEC member states would continue to be enforced in the event of a shortage when the European Commission would undertake to share out stocks equitably. The Euratom Supply Agency, which in the past has been successful in negotiating long-term uranium supply contracts with Australia, Canada and the United States, would continue to supervise and negotiate such deals. **Jasper Becker**

Stanford cuts comment on patent

Washington

Stanford University, citing "erroneous public impressions" concerning the Cohen-Boyer biotechnology patent, last week ordered the US Patent and Trademark Office to keep secret all future action on its pending application. The move came just before the patent office was expected to announce its latest action on the application, which it tentatively rejected last summer.

Normally, all actions on a patent application are secret until a patent is granted but Stanford originally waived its right to secrecy. According to Robert Rosenzweig, Stanford's vice-president for public affairs, the "central issue" in Stanford's decision to close the file was "the dispute over inventorship" (see *Nature* 25 November, p. 303). "We thought that had some potential for damaging people's reputations unnecessarily", he said. Dr Robert Helling, a co-author of the key scientific paper on which the patents are based, is now claiming that he is a co-inventor; the confusion over Helling's role was cited in the patent office's tentative rejection.

Rosenzweig said that keeping the file open had been "an experiment with some risk" and that "the experiment has failed". He said, "when the application process is completed, the file will be opened for public inspection. Until then, it is better that it not emerge in piecemeal fashion."

Stanford has already sold licences to the first Cohen-Boyer patent, issued in December 1980, to 73 companies for an initial fee of $10,000 per year. That patent, which covers the basic process for inserting foreign DNA into bacteria, is similar to the second one, now pending, which covers the transformed bacteria products. Thus there has been concern that the flaws the patent office cited in the second patent could invalidate the first patent. The licensees have discussed the possibility that Stanford should open the first patent for reexamination and meanwhile hold the licence fees in escrow. Rosenzweig said that the licensees would be kept informed of the progress of the second patent. **Stephen Budiansky**

Chemical warfare

Fight amongst Finnish

The publication last week of the report of the United Nations on allegations that the Soviet Union and Vietnam have been using chemical warfare against insurgents in Afghanistan and South East Asia has caused some embarrassment to the Finnish foreign minister Paer Stenbaeck, who refused to let his ministry assist the enquiry. According to the independent newspaper *Laensi-Savo*, the minister was "mixing up the work of Finland's Technical Research Institute with our foreign policy's credibility".

The implication from comments in the Finnish media is that there has been a conflict over the freedom to research, with Mr Stenbaeck forbidding the project and the head of the Technical Research Institute (VTT) Dr Pekko Jauho insisting on the research going ahead.

During the past ten years, Finland has built up, under the supervision of the foreign ministry, a chemical warfare-monitoring capability which involves a number of laboratories and institutions — mainly civilian — including VTT. This capability, the Finns hope, will ultimately be used under the auspices of international agreements banning chemical warfare. Meanwhile the Finns have built up a considerable body of experience, and it was reasonable, after the pledges of successive Finnish governments to support the United Nations in every aspect of its peacekeeping role, that the UN enquiry team should approach the Finns for assistance in analysing vegetation and blood samples from South-East Asia.

But Mr Stenbaeck was reluctant to let his ministry help. He felt, apparently, that without the guaranteed conditions for impartial and neutral verification which would presumably be embodied in a future treaty, it could damage his ministry's credibility to be involved in such a contentious issue as the allegations of chemical warfare in South East Asia. In particular, he had considerable doubts about the provenance of the samples, which had been brought to Finland without prior notification or agreement. The sample delivered to the Finnish Foreign Ministry was accordingly returned to the United Nations unopened, apparently on Mr Stenbaeck's direct instructions.

The other two samples were delivered to two scientists working for VTT, Professor Tor-Magnus Enari, an expert on *Fusarium*, and Professor Rolf Rosenbere, a physicist working in neutron-activation analysis. VTT, a government establishment responsible to the ministry of trade and industry, operates a wide programme of contract research and development for both Finnish and foreign customers, and the UN commission was accepted as a purely commercial proposition. The work duly went ahead, giving, as it turned out, entirely negative results. **Vera Rich**

UK nuclear power

PWRs "safe"

A new report from the Advisory Committee on the Safety of Nuclear Installations (ACSNI) concludes that the Central Electricity Generating Board (CEGB) will be able to reach acceptable standards of safety for Britain's first pressurized water reactor (PWR), but draws attention to a number of areas in which it feels further work will be needed. In this respect it is substantially in agreement with the Nuclear Installations Inspectorate (NII) report earlier this year.

Some of the points raised by the document are sure to be used by objectors at the forthcoming public inquiry into the proposed PWR at Sizewell to embarrass CEGB, but the board seems confident that the questions raised in the ACSNI report have been answered since the end of 1981 (the latest date for ACSNI's evidence). This may explain some of the report's apparent ambiguities. In particular, CEGB's design proposals in its Preconstruction Safety Report have already been modified to include a double-containment system for the reactor pressure vessel, in accordance with current French and German practice.

ACSNI, set up to report to the Health and Safety Commission, attempts only to review the technical work of others and considers only selected aspects of PWR safety. The areas considered, by separate study groups, were the integrity of the pressure vessel, the plant/operator interface, and fuel processing. Most of the potential problem areas highlighted by ACSNI lie in the first two catagories. Besides echoing NII's insistence on the highest achievable quality control of steel components in the reactor vessel itself, the report asks for equivalent standards to be applied to the whole of the coolant system. Standards for testing the integrity of welds are questioned, and more work is requested on degraded core phenomena. One of ACSNI's most significant criticisms of the CEGB Preconstruction Safety Report concerns the possibility of multiple breaks in the steam generator tubes, a consideration apparently excluded by CEGB on the grounds of unlikelihood. Since that time such an accident has in fact happened, and resulted in the release of some radioactivity.

On the subject of the plant/operator interface (one of the main causes of the accident in the PWR at Three Mile Island) the report makes recommendations about management and training schemes, and

Japan plans DNA database

Washington

Japan's entry into the field of molecular genetics may include a central data bank for DNA sequences. Storage of these complex sequences in computers and their statistical comparison have opened up new analytical possibilities in the field.

Some Japanese scientists attending a recent workshop in Aspen, Colorado, expressed an interest in starting such a database, and the scientists who run the new US database at the Los Alamos National Laboratory have welcomed their interest. The Japanese Ministry of Education may decide on 7 January 1983 to fund the project.

The database, likely to be located at the University of Tokyo, could be linked electronically to the Los Alamos database and to that run by the European Molecular Biology Laboratory (EMBL) at Heidelberg, West Germany.

A crucial question is which sequences it should collect. It would clearly be useful to collect the sequences published — sometimes in Japanese — in the Japanese scientific literature, which are generally unavailable to the groups at Los Alamos and Heidelberg. On the other hand, the number of sequences published in the Japanese journals is so far rather small, so that the database may be expanded to include those published abroad as well.

The Los Alamos database is supposed to contain all published sequences by July 1983, according to the terms of the contract that the US National Institutes of Health awarded to Bolt, Beranek and Newman for the Los Alamos-based project, known as GenBank. Walter Goad, the principal investigator at Los Alamos, said last week that sequences with an estimated 750,000 bases had been entered into his system, and that by the July 1983 deadline, it may include as many as 2 million bases. The GenBank database has just been announced "as available to the public for a nominal fee". **Deborah Shapley** says that a simulator designed to train operators specifically in the control of PWRs should be operational before the reactor is commissioned. The CEGB is again happy that it can satisfy this request. The difficulty is, as the report points out, that no-one knows exactly how the reactor will behave in extreme fault conditions, so a simulation of such events can only be approximate.

NII has welcomed the ACSNI report as a valuable input to its own examination of the CEGB case, but says that all the areas mentioned by ACSNI are currently receiving attention anyway. The inaccessability of detailed current CEGB safety proposals is one major headache for objectors at the inquiry. **Tim Beardsley**

US energy research

Cuts demand

Washington

The Office of Management and Budget (OMB), still putting the final touches to the President's budget for fiscal year 1984, has proposed substantial cuts in research spending on fossil and solar energy and energy conservation. The OMB proposal, which is still subject to an appeal by the new Secretary of Energy, was leaked last week by congressional sources.

The proposed cuts are similar to those proffered by OMB for the past three years and which Congress has chosen to ignore. In addition to eliminating all demonstration projects and all federal government involvement in service programmes (for example grants to communities to provide insulation of residences), the cuts would hit the following research areas:

- Fossil energy. Research on combustion, coal liquefaction and gasification, and coal clean-up would be cut from the current level of approximately $300 million (as approved by the House and Senate appropriations committees for fiscal year 1983) to $106 million, the same level that the President requested for 1983. Most of these funds go to research contracts with industry.
- Solar energy. Long a target of Reagan Administration budget-cutters, solar research would also be held to the level of the 1983 request, $72 million. Congress is heading for an appropriation of $180 million for 1983. The Department of Energy itself had asked for $87 million for fiscal year 1984.
- Conservation and renewable energy. OMB wants a limit of $36 million on this programme which has already been severely cut by the removal of all non-research components. Of the $383 million appropriated by Congress for conservation in fiscal year 1982, $156 million was for research; the Department of Energy (DoE) requested $51 million for fiscal year 1984.

DoE is reported to be planning an appeal, at least for the fossil and conservation budgets. The final budget will be released in January. **Stephen Budiansky**

Soviet economy

Size costs dear

Last week, an article in *Pravda* by N. Kulagin, a hitherto obscure researcher at the N.A. Voznesenskii Financial-Economic Institute in Leningrad, evoked a flood of speculation in the West that, under its new leadership, the Soviet Union might reverse its traditional bias towards larger and more comprehensive industrial enterprises. Such an article is a standard method of launching a new policy trend, without going as far as to condemn the old.

In this case, under the title "It is hard to be universal", Kulagin compares the Soviet preference for "gigantic multiprofile plants" with the development in the West of small specialized factories which cooperate with major industry by providing specialized components and services.

The large Soviet enterprises, each with its own staff of repairmen, instrument makers and transport-workers, is, Kulagin pointed out, wasteful of resources — in the Soviet machine building industry, for example, some 38 per cent of staff are engaged in such ancillary work, compared with only 11 per cent in the United States.

The type of centralized planning practised in the Soviet Union, as well as the vast investment originally needed to bring a number of sectors up to world level, undoubtedly has had much to do with the preference for gigantic plants. Such factories produce not only the goods specified in the State Plan, but also a large part of the components and auxiliary equipment they require. As Kulagin points out, these cause considerable difficulties but do not show up in the total output figures of the plant, thus making nonsense of the economic indicators.

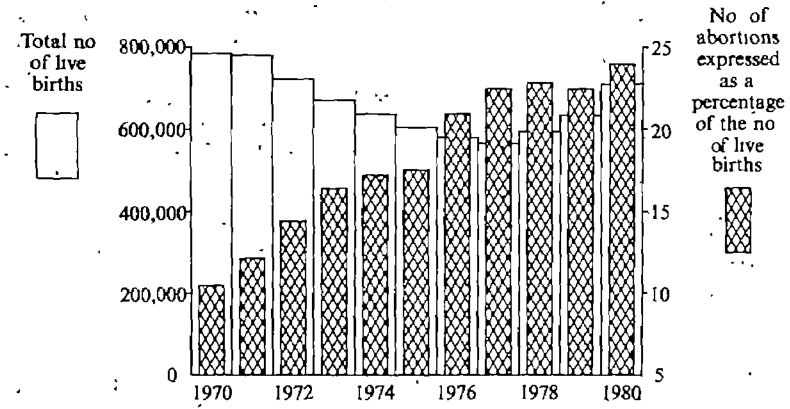
Furthermore (a point not developed by Kulagin) if a "giant" industrial plant in Leningrad needs say, bolts with special performance parameters, it will commission some Leningrad institute to do the appropriate research, while a plant in Vladivostok, needing a precisely similar bolt, will commission the appropriate institute there. The duplication of research is considerable, particularly because, officially, Soviet scientists are not supposed to discuss their unpublished results with colleagues from other institutes. The introduction of small-scale plants, each specializing in the production of specific components, as advocated by Kulagin, could cut research costs considerably.

The implementation of the latest results of research and development — the major bottleneck in the modernization of Soviet industry — could also be carried through more effectively, in a network of small-scale plants, since the individual shut-downs for retooling could be better staggered.

And, perhaps most important, according to Kulagin, the costs of components made in one's "own" factory are frequently double what they would be from a "specialized" factory.

The concept of a changeover to smaller production units is not — in spite of the commentators last week — entirely new. The trend has slowly been taking shape over the past ten years, and several planning conferences have been held on the theme, one of which proposed the formation of a special Ministry of Interbranch Production to run the small component-producing plants. This has so far, however, failed to materialize, owing to bureaucratic difficulties inherent in the transfer of plants from one ministry to another. **Vera Rich**

Increasing abortion rate in Britain



The annual number of abortions performed in England and Wales has risen from 82,730 in 1970 to 159,503 in 1980. In 1979 25 per cent of abortions were performed on women aged under 20 although only 9 per cent of all mothers fall inside this bracket. Not surprisingly, 60 per cent of the abortions were performed on women of between 20 and 34 — the age bracket which includes 85 per cent of mothers. The highest abortion rate is for women over 45 where the number of abortions actually exceeds the number of births. Source: *Health and Personal Social Services Statistics for England 1982* (HMSO: £7.50).

UK engineering

Institutional scrap continues

Britain's 200,000 chartered engineers are currently voting in a postal ballot on a recommendation from the board of the Council of Engineering Institutions (CEI) that control of its register of accredited engineers should be handed over from its own Engineers' Registration Board to the new Engineering Council, set up in the wake of the Finniston report. The outcome of the vote is far from certain; however, it is clear that if the recommendation is approved, CEI, which represents members of all the chartered engineering institutions, will have little reason to continue its existence.

The objects of the Engineering Council, listed in its Royal Charter, are to "advance education in and promote the science and practice of engineering . . . for the public benefit". Its members, who are appointed initially by the Secretary of State for Industry, will form a number of standing committees. The main purpose of these committees is to consult with industrial companies and educational establishments as well the existing professional institutions.

Engineering Council on 30 September detailed its future intentions in all its areas of responsibility including the setting up of a register of engineers. The statement clearly was influenced by the previously expressed concern of CEI that the views of its members should be assured of an adequate hearing on the new council and that existing titles would be protected: CEI will ask the existing professional institutions to oversee the awarding of titles, and their independence is explicitly recognized.

However, the Engineering Council's document fails to satisfy the expressed wishes of CEI that the titles of Technician Engineer and Engineering Technician should be awarded only to members of institutions. Furthermore, the document fails to guarantee the CEI's wish for self-regulation for the profession. Despite this, the CEI board approved the move with a 25 to 10 vote, although some members apparently felt they had very little choice. Now a two-thirds majority in the postal ballot of members is needed to implement the transfer.

Mr Gerald Mortimer, CEI chairman, is satisfied that "somehow or other" the views of professional engineers will gain an adequate hearing in the new Engineering Council. The move has been welcomed by the Fellowship of Engineering, which points, out that "it will be essential for professional engineers to use their influence in the institutions to maintain standards".

US research

Basic physics in doldrums

Washington

Basic physics research in the United States is declining in quality compared with Europe, according to a new study by the US Office of Naval Research (ONR). Moreover, US industry is "just not playing the game" in basic physics, with the exceptions of Bell Laboratories and the IBM Corporation. Finally, the study suggests that the US Department of Defense has supported less and less of the important contributions to basic physics in the past decade.

These are the gloomy findings of a study counting the affiliations of all the contributors to *Physical Review Letters* (PRL), a leading journal of research in basic physics, between 1958 and 1979. Author Ted G. Berlincourt of ONR and his colleagues also counted the affiliations of contributors to the leading journal for applied physics, *Applied Physics Letters* (APL), from the time it was founded in 1962 until 1979 and found the same trend.

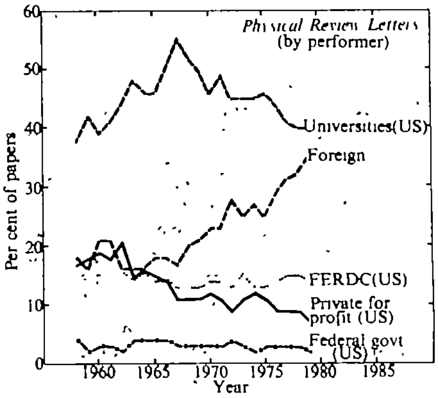
The accompanying figure shows the most striking finding of the PRL count. The journal published an increasing number of papers each year until 1968, when the number levelled off at approximately 1,000. Yet from the mid-1960s onward, the number of foreign contributors rose steadily and was still rising in 1979 when the count stopped. The number of US contributors to the journal decreased correspondingly.

The ONR study speculates that this dramatic shift in foreign contributions might be caused by editorial policy. But George Trigg, who has been editor of *Physical Review Letters* since 1966, says no decision was made either to take more foreign contributions or to level off at 1,000 papers per year. "It has always puzzled me, because in the last 15 years the numbers of articles in other journals has increased" Trigg said. Apparently, no more than 1,000 are good enough to get through PRL's review system. The probable conclusion is that fewer and fewer US papers have passed muster.

Institutions outside the United States whose scientists are most successful in publishing in PRL are, in order, the Kernforschungsanlage Jülich in West Germany, the Atomic Energy Agency of Canada, and IBM Switzerland.

Berlincourt and his co-authors see several alarming trends emerging from their study. The "vigor" shown by basic physics outside the United States, and the parallel "vigor" of applied physics, "will without doubt be translated into stiff competition in all technology-dependent international arenas".

The applied physics work of US industry, they note, is "near stagnation". Private companies in the United States have contributed a declining proportion of the papers in *Applied Physics Letters*. There has also been a decline in industry's contributions to *Physical Review Letters*; when Bell Laboratories' and IBM's contributions to PRL are taken out, industry has been contributing only 20 papers per year to PRL. IBM's and Bell Laboratories' contributions have declined since 1975.



From: "Performer affiliations and funding sources for research" by Ted G Berlincourt, Harold Weinstock, Francis Narin, and Samuel R. Reisher.

The paper also notes that the number of physicists supported by the Department of Defense (DoD) contributing to PRL, the basic journal, declined precipitously after 1967, the year when the Mansfield Amendment determined that DoD should support only research directly relevant to military requirements.

Although the Mansfield Amendment was in effect for only two years, the trend it accelerated "had not been reversed by 1979, some eight years after the expiration of the Mansfield Amendment", even though senior defence officials since the Ford Administration have been saying they wish to rebuild DoD's ties to the university basic science community.

"The very marked erosion of DoD support for PRL-type basic physics . . . implies a significant decoupling of the defence establishment from the cutting edge of the scientific discipline, which, probably more than any other, has yielded the seminal scientific advances on which revolutionary military development are based. . ." says the study.

The poor performance of industry and DoD in basic physics research may be correlated because each year DoD reimburses industry for some fraction of relevant research through the Independent Research and Development funds. So US industry has invested very little — even of its DoD money — in basic and applied physics. Overall, the study suggests that the recent rise in US defence research funds may not automatically reinvigorate US basic physics.

CORRESPONDENCE

Whose game?

Sir — In his review of J. Maynard Smith's *Evolution and the Theory of Games*, R.C. Lewontin[1] refers to his own "introduction in 1961 of the apparatus of game theory into evolutionary biology". Students of the history of ideas may be interested to know that, about a week after a seminar on this subject given here by Lewontin in 1962, and shortly before R.A. Fisher's death here, the latter also gave us a seminar on the same subject. With the "characteristic modesty" to which Lewontin also refers in his review, Fisher pointed out that not only had he introduced game theory ten years before von Neumann[2] but he had also discussed it in relation to evolution before Lewontin: this was in a paper that was given to the 30th session of the International Statistical Institute at Stockholm in 1957 and subsequently published twice[3,4]. I shall leave readers to judge for themselves the importance of these contributions but would like to record the main example that Fisher gave us at the seminar since I think it was never published and may be of widespread application to the explanation of some life cycles that are ecological enigmas. He suggested that the massive production of fruit which occurs infrequently and at random in northern deciduous forests ("mast years") illustrated the principle that, if an opponent (in this case nut-eating animals) cannot be defeated, then it is advantageous to randomize vulnerable activities (nut-production). His biographer[5] records Fisher's fondness for pigs and, since these animals used to be a major beneficiary of mast years, I suspect that there is a connection.

On Time defended

Sir — I was interested to read the review by P.W. Atkins in the 11 November issue of *Nature* (p.133) criticizing *On Time* by Michael Shallis, since I have recently read and enjoyed the book. I found the tone of Atkins's remarks derogatory in the extreme.

A point that I would like to make is that scientists of the first category (as defined by Atkins) are so often the blinkered, passive donkeys of their professions who will deny a goodly portion of life's experiences because it is not possible to measure them quantitatively. I imagine that had Atkins been around at the time of Galileo he would have been enthusiastically pouring scorn on the "outrageous" heresy of a heliocentric planetary system for much the same reasons as he scorns Shallis's attempt to look at subject matter which is regarded as "unscientific". It is so easy to be an Atkins and to use these reductionist attitudes to stay safely within the comfortable known behaviour patterns of the peer group. It is very difficult to be a Shallis and to admit that we do not know it all and that there are areas where we can only wonder and conjecture.

I would like to know what indications Atkins has managed to find in the book that Shallis "disregards the successful continuing progress of modern science". It seems strange that Atkins should carp about this as his own popular lecture on all science rapidly coming to a single all-embracing conclusion, leaving scientists as "keepers of the truth", leaves one with the strong impression that here at least is one scientist who has come to a grinding halt and who one would expect to welcome, not deride, others whom he sees, however wrongly, as being in the same boat.

On Time is a well written, thought-provoking book which deserves better than to have attracted such a destructive onslaught.

V. Ann Buckle

Wokingham, Berks, UK

Cometary record

Sir — In my News and Views article on the recovery of Halley's Comet (*Nature* 25 November, p.318), I stated that Halley's Comet (at recovery 11.04 AU away from the Sun) was the most distant comet ever seen, beating the previous record held by Comet Stearn (1927IV). I was wrong and must thank Professor R.A. Lyttleton for pointing out my error. According to S.K. Vsekhsvyatskii (*Physical Characteristics of Comets*), 1927IV was last seen on 13 March 1931 when it was 11.53 AU from the Sun. So Stearn is still the record holder. For Halley to usurp its position we will have to observe it into August 1989.

University of Sheffield,
Sheffield, UK

Grouping Darwin

Sir — In his autobiography *The Gates of Memory* Sir Geoffrey Keynes[1] revealed that the family he used to illustrate the inheritance of the ABO blood groups in his book *Blood Transfusion*[2] was his own and his wife's. Charles Darwin was Lady Keynes's grandfather.

Of Charles and Emma Darwin's five children, four were blood-group O and one, George, Lady Keynes's father, was untested. Charles and Emma must therefore each have carried at least one O gene, and of their grandchildren, only George's children could provide further relevant information, since George's blood-type was not determined.

George's wife Maud was blood-group A, and of their four children, two were O (one was Lady Keynes) and two were A. Maud must therefore have been of genotype AO, and George must have carried at least one O gene. In the published genealogy only the two "O" children themselves have children, who therefore provide no further information about George.

The possibilities are therefore that Charles and Emma Darwin might each have been AO, BO or OO, and so might their son George. For each of the nine possible genotype-pairs for Charles and Emma we can compute the probability that they had four OO children and a fifth who on marrying an AO had two O and two A children (and hence certainly carried on O gene).

The calculation of these probabilities is entirely straightforward and I therefore omit the details; it should be noted that because the only person other than Charles and Emma entering the genealogy except as a child is of known genotype (Maud, who is AO), the probabilities are not functions of the unknown gene frequencies in the general population. This is, of course, unusual in this type of problem.

The resulting probabilities expressed relatively are the likelihoods[3] of the several hypotheses:

Relative likelihoods of Charles and Emma Darwin's genotypes

OO × OO	16,384
OO × AO or AO × OO	800
OO × BO or BO × OO	544
AO × AO	43
BO × BO	19
AO × BO or BO × AO	26

It will be seen that it is overwhelmingly likely that both Charles and Emma Darwin were blood-group O, the next most likely hypotheses being over 20 times less likely.

Acidity and alkalinity

Sir — "Acidity" is an awkward term when used as a heading for discussion of effects brought about by varying hydrogen ion concentration. It is limiting in first appearances because it also doubles in general usage as a term implying only the acid end of the scale. The older term "hydrogen ion concentration" does not itself convey the concept we are often trying to put across; that which we neatly sum up in the jargon term "*p*H".

When we are heading manuscript sections for variables such as "temperature", "pressure" and so on, the heading word "*p*H" seems too short. We tend to get around the problem by writing "effect of *p*H". Some manoeuvring is also required to ensure that we do not have *p*H as the first word of a sentence, since we cannot capitalize it.

For the parallel concept of oxidation and reduction we rarely use the symbol "E", meaning the oxidation–reduction potential, in a sentence. Certainly the phrase "transferable electron potential" is an unusual heading. The convenient word "redox" has come into common use.

Therefore, by analogy, I propose the term "alkacidity" as a convenient word to express an important idea in brief.

NEWS AND VIEWS

A superfast new pulsar

from David J. Helfand

FIFTEEN years ago last autumn, Morse-code-like signals pulsing with extreme regularity were received at a Cambridge radio telescope — pulsars had been discovered. Although the first such object was dubbed an LGM (for Little Green Man), a total of four such sources had been identified by the time the discovery was announced in February 1968 and the signals were soon explained, without recourse to the presence of extraterrestial intelligence, as lighthouse-like flashes from highly magnetized rotating neutron stars. With nearly 350 objects now catalogued, it might seem surprising that the detection of a new pulsar would generate much excitement. But PSR1937+214, whose discovery is reported by D. Backer *et al.* on page 615 of this issue of *Nature*, is not typical; it is rotating at an astonishing 642 times a second and may well represent the first of a whole new class of objects.

The story of the discovery is one of perseverance combined with a dash of good luck. The source first appeared in the fourth Cambridge catalogue of radio emitters as 4C21.53. Its peculiarity was first noted in 1972. Using the Cambridge interplanetary scintillation telescope with which pulsars were discovered, A. Readhead and A. Hewish reported[1] that the source 'twinkled' in the interplanetary medium, unusual behaviour for an object lying in the plane of the Galaxy where interstellar material generally broadens the apparent angular diameter of compact sources and destroys the IPS modulation. Backer's attention was drawn to the source in 1979 following a report[2] that it had a steeply rising spectrum at low radio frequencies which, along with the very small diameter implied by the IPS measurement, is a characteristic of radio pulsars. In perusing the literature, he noticed that 4C21.53 was roughly coincident with a diffuse region of emission with a contrasting flat radio spectrum. This combination of a scintillating, steep-spectrum source and a diffuse flat-spectrum region was strikingly reminiscent of the Crab Nebula and its embedded 33 ms pulsar, the youngest and fastest pulsar then known.

This area of the sky had been searched for pulsars in 1973 by R. Hulse and J. Taylor, then of the University of Massachusetts, using an extremely sensitive system at the Arecibo Observatory 1,000-foot radio telescope. As in most of the large-scale pulsar searches conducted to date, the workers would have found it impossible to detect a new pulsar with a period significantly shorter than that of the Crab since the threshold period for the search was ~ 30 ms. This constraint is usually dictated by limitation on computer time, but this had not been deemed a serious problem: there are no other objects like the Crab Nebula within the search range (~ 10^4 light yr), and it was thus assumed that there were no younger and faster pulsars to be found. The assumption, that all fast pulsars are young, may have been the critical flaw in the argument.

In 1979 Backer conducted a search for a shorter-period source in 4C21.53 at both the Owens Valley Radio Observatory and at Arecibo without success. His interest persisted, however, and, in November, some tantalizing earlier results from S. Kulkarni and C. Heiles were followed up with a search for interstellar scintillation which has, to date, only been observed for pulsars. Deep modulation was found and the following day, the periodicity of 1.5578 ms was confirmed.

The source is remarkable in many ways. The rotation rate is within a factor of about 3 of centrifugal break-up. The star's surface is moving at ~ 20 per cent of the speed of light and the rotational kinetic energy of the object is nearly 10^{52} ergs, comparable with the entire energy output of a supernova explosion. Furthermore, this superfast pulsar shows no evidence of the encircling supernova remnant expected to accompany the creation of such an object.

A measurement of the pulsar's slowdown rate is critical in addressing several important questions including the object's age, origin and energy loss mechanism (for example, gravitational waves versus magnetic dipole radiation and energetic particles). The limit quoted by Backer *et al.* implies a period derivative $\dot{P}$ $<10^{-15}$ seconds per second (s s^{-1}), a factor of several hundred smaller than the Crab. J. Taylor of Princeton University has recently taken his equipment used in monitoring the binary pulsar to Arecibo and has already lowered this limit substantially in a week's observation. It thus appears that, despite its huge store of rotational kinetic energy, the pulsars energy output is quite small. Optical observations, also reported in this issue, and X-ray data taken with the Einstein Observatory by R. Becker suggest that the high-energy emission from this object both from within the magnetospheric (that is, pulsed) and from a pulsar-powered synchrotron nebula is several orders of magnitude less than that from the much slower Crab pulsar. These results will dampen the initial excitement caused by the discovery among the experimental general relativity community, where the early report[3] of a high spindown rate led to quickly drawn plans for gravity wave detectors tuned to the pulsar frequency.

Backer *et al.* suggest that the pulsar and the nearby diffuse source (now known to be an HII region) may be associated, with the latter excited by an escaped binary companion of the fast pulsar. From the separation of the two sources and using a typical pulsar velocity, they infer an age for the pulsar of ~10^4 yr. The case is far from compelling, however. More recently, A. Alpar, M. Ruderman and J. Shaham of Columbia University, together with A. Cheng from Rutgers University, have proposed a scenario in which the neutron star is billions of years old and was reactivated as a pulsar after having been spun up by accretion from a companion. In a letter to appear in the next issue of *Nature* they suggest that the source is the remnant of a galactic bulge X-ray binary system. The standard scenario for bulge sources consists of an evolving low-mass star spilling matter onto a neutron star with a very low magnetic field. For such an object, the Alfven radius at which the magnetic field dominates the inflowing matter is very close to the stellar surface, allowing for a large transfer of angular momentum to the star, spinning it up to millisecond periods. The ultimate spin rate is a function principally of the field strength and the mass transfer rate. Once the accretion stops as a result of the dissipation or ejection of the companion, the pulsar will begin to spin down again. But with its low field, the spindown time will be very long, preserving a population of old rapidly spinning pulsars.

The strength of this picture is that it offers a prediction of the current magnetic field strength and, thus, of the period derivative for such a source. The model gives the right answer for $\dot{P}$ for each of the three known binary pulsars, all of which have anomalously low spindown rates for their short periods. For 4C21.53, the prediction of $\dot{P} < 5\times10^{-20}$ s s^{-1} will be testable within a few months.

Many questions remain to be answered about this exciting new object and searches for other examples are already being planned. Future studies will focus on what such sources can tell us about the mechanism of pulse emission, neutron star interiors, and the origin and evolution of pulsars. At the moment, though, 4C21.53 serves as a reminder of the richness of the physical Universe in which each unexplored corner of parameter space holds a new mystery for the astrophysicist to ponder. □

'Lucy' jilted?

from M.H. Day

WHAT'S a girl to do if her date lets her down? This question often has to be answered by girls who have waited in vain — but the question of interest here is has 'Lucy' (or to be more precise her slightly older 'relations') waited 3.3 or 3.6 million years before her date with Don Johanson, Yves Coppens and Maurice Taieb? These three, the leaders of the French/American expedition to the Hadar region of Ethiopia, have been responsible for the recovery of the early hominid material, known collectively as *Australopithecus afarensis*, from deposits that were originally said to range in age from 2.6 to 3.1 million years before the present. The famous Lucy is said to be part of that species, as are Mary Leakey's earlier Laetoli hominids from Tanzania[1]. Earlier this year, however, it was suggested that the dates of the basalts from the Hadar series had been underestimated by as much as 300,000–600,000 years, bringing the earliest date of the Hadar site much closer to that of Laetoli, the site from which the *A. afarensis* type specimen was chosen[2], this species being regarded by some as representing the common ancestor of the hominid stem.

An article[3] in this issue of *Nature* (p.631) now questions this revision of the lower end of the temporal range of the Hadar hominids on grounds of stratigraphical correlation between the Hadar Formation and sites in the Lake Turkana Basin, together with faunal studies that may be consistent with the younger rather than the older age for the bottom of the Hadar sequence. F.H. Brown reports the results of microprobe and X-ray fluorescence analysis of a group of volcanic tuffs from the Koobi Fora Formation (Tulu Bor), the Shungura Formation (Tuff B) and the Usno Formation (Tuff U-10). All these air fall tuffs are the result of volcanic eruptions and all are found in the Lake Turkana Basin of northern Kenya and southern Ethiopia. Further north in Ethiopia, the Sidi Hakoma Tuff has also been sampled from the Hadar site and added to the comparisons. The microprobe analyses of major and minor elements and the X-ray fluorescence analyses of minor and trace elements show remarkable correspondence in all of the tuffs examined and lead to the view that all were the result of broadly contemporaneous events and thus may indicate isochronous litho-stratigraphical horizons. This is said to produce a 'direct lithostratigraphical tie' between the Hadar Formation and the Lake Turkana region which can help to date the fossil faunas of the two areas, including the hominids.

The palaeomagnetic evidence shows that the three tuffs from the Lake Turkana basin are all of normal polarity and they are thought to lie in the Gauss Normal Epoch, having therefore an age of between 3.17 and 3.42 million years. The Sidi Hakoma Tuff also has a normal polarity. The two reversed zones above the Sidi Hakoma Tuff and their equivalents in the Shungura and Usno Formations have been regarded as the Mammoth and Kaena Events.

Potassium/argon (K/Ar) and fission track dates from the Hadar Formation are said to be consistent with those identifications with one interesting exception, the 3.6 Myr date for the Type B sample of the Kadada Moumou Basalt (KMB)[2]. The date for this layer has been revised by Brown[3] to 3.12 Myr by applying a 3.5 per cent upward 'correction' to the 3.01 Myr date for the original Type A sample of the KMB, so that the reversed polarity of the KMB layer can sit conveniently in the Mammoth Event rather than be attributed to the underlying Gilbert reversal as it would be at 3.6 Myr. In the Lake Turkana Basin the palaeomagnetic identifications also apparently accord with the K/Ar dates on the tuffs, with the exception of the date of Tuff B10 of the Shungura Formation which is said to be 'too old' at 3.75 Myr. This tuff is one of the uppermost units of the Shungura Formation and lies just below Unit B10, which produced most of the fauna from Member B referred to in a second paper[4] published in this issue of *Nature* (p.633) that deals with the age of the Hadar Formation.

In these days of 'high-tech' science, there is something delightfully anachronistic about consulting an assemblage of fossil bones to support or disprove a numerical age produced by radiometric means. This was exactly what happened at Koobi Fora, however, where it took the 'pig clock'[5,6] to sort out the correct date for the KBS Tuff. Biostratigraphy, therefore, still has an important part to play in geochronology, since its cumulative effect may also be enhanced by comparisons from several adjacent sites. In the paper by Boaz, Howell and McCrossin (p.633), two large-mammal faunal lists, one from the Usno Formation (Lower B) and the other from Shungura (B10), have been compared with the Hadar assemblage and with each other by means of faunal similarity coefficients.

The Usno and Shungura comparative assemblages are given 'best-fit' K/Ar and palaeomagnetic dates of 2.92 and 3.15 Myr respectively and thus a time difference of about 0.2 Myr. The results show firstly that the Usno and Shungura assemblages are nearer to each other than either is to Hadar and secondly that by any test the Hadar and Usno faunas are closer than the Hadar and Shungura B10 faunas, suggesting that the Hadar fauna is closer to the older of the two dates. Unfortunately, sites such as Laetoli, Kanapoi, Mursi and Ekora, with a range of 3.2–4.0 Myr, cannot be compared with Hadar at present since their inventories are not complete. The faunal evidence, as far as it goes, therefore, seems to be consistent with the date for the Hadar site put forward by Brown, yet a pre-Usno date for Hadar is prudently not rejected. It seems that the correlative stratigraphical and faunal case for a younger lower limit for the Hadar site is interesting but not compelling.

What, then, would be the significance of this proposed revision (or perhaps reversion is a more appropriate word) of the dating of the Hadar site for hominid evolution? All seem agreed that the bulk of the Hadar hominids are older than 2.88 Myr. The lower limit of the range at Hadar is either 3.12 or > 3.6 Myr, a difference of 400,000 years or more with a possible span of 240,000–720,000 years at this site. This means that the Hadar sample of hominids is drawn from either a quarter or nearly three quarters of a million years; this must colour the views of those who would tackle the question of whether the Hadar sample is homogeneous and monospecific. Indeed, in relation to the Laetoli site, a gap of 370,000 years has re-opened in the evolutionary history of *A. afarensis*.

As well as the correctness of including the Laetoli hominid material in the same specific category as that of the Hadar sample, the question of the age of the Makapansgat site in the Republic of South Africa now begins to become relevant. A younger date for Hadar, if proven, coupled with an older date for Makapansgat[7,8], could make it uncertain that Makapansgat *Australopithecus africanus* is more recent than Hadar *Australopithecus afarensis*. Laetoli is, of course, still older than either site; but if the specific unity of the Hadar *A. afarensis* sample or the inclusion of the Laetoli hominids in that sample is shown to be incorrect, then *A. afarensis* could be a stem form in name alone. The folly of selecting a type specimen both geographically and temporally separated from the largest and best fossil sample would then be exposed once more.

To let a girl down on her date is bad enough, but to get her name wrong when you do arrive would be intolerable! ☐

Mouse and supermouse

from Jeffrey G. Williams

THE mice displayed on the cover of this week's *Nature* are littermates but one has a bodyweight almost twice that of its sibling. They differ in that the larger mouse carries a hybrid gene containing the promoter of the mouse metallothionein-1 gene fused to the structural gene for rat growth hormone (see p.611). The 'transgenic' mouse was produced by injecting the hybrid gene into the pronucleus of a fertilized egg. Mice carrying the gene display very high levels of the fusion mRNA in their liver, high levels of growth hormone in their serum and an elevated growth rate. This is the first time that genetic engineering has been used to alter the phenotype of an animal in such a profound manner and is the culmination of a series of elegant experiments performed by Palmiter, Brinster and their colleagues over the past few years. There are almost certain to be great scientific and practical benefits from the application of genetic engineering techniques to animals. It is essential, however, to stress that there are limitations on what can be done — and more important, on what is worth doing.

When cloned genes are introduced into fertilized eggs by micro-injection a proportion of the mice that develop will carry the gene. The injected genes become chromosomally integrated but they are not found at the normal, nor even at a unique, location and the number of gene copies per cell also varies from animal to animal. The mice that develop from the injected eggs may also be chimaeras in which only some of the cells contain foreign DNA. However, a proportion of mice do transmit the newly acquired gene to their progeny and it s thus possible to produce mice containing the gene at a defined position in every cell.

The product of the mouse metallothionein-1 gene is a small cysteine rich polypeptide that binds heavy metals and is thought to be involved in zinc homeostasis and resistance to heavy metal toxicity. It is present in most tissues of the mouse, but the highest levels are found in liver. Transcription is inducible by heavy metals and glucocorticoids. Experiments reported earlier this year (Brinster *et al. Nature* **296**, 39; 1982) used a hybrid gene to establish that the sequence elements required for heavy metal inducibility lie within a stretch of DNA ninety nucleotides upstream of the start point of transcription. The hybrid gene contains a segment of the 5′ non-coding region and upstream sequences derived from the metallothionein-1 gene. Both were fused into the 5′ non-coding region of the structural gene for herpes virus thymidine kinase to provide a readily assayable enzymatic activity. The hybrid gene was injected into fertilized mouse eggs which were incubated with cadmium as an inducer and then assayed for thymidine kinase activity.

The same fusion gene was used in two subsequent studies in which micro-injected fertilized eggs were re-implanted into foster mothers (Brinster *et al. Cell* **27**, 223; 1981; Palmiter *et al. Cell* **29**, 701; 1982). A high proportion of mice which carried the fusion gene expressed thymidine kinase in the liver. The activity was inducible with heavy metals but not with glucocorticoid hormones. For unknown reasons, in the progeny derived from these mice the expression of thymidine kinase was diminished or abolished in some cases and enhanced relative to the parent in others.

The metallothionein-growth hormone fusion gene was constructed using exactly the same principle as the *tk* fusion gene, with the genes being joined in their 5′ non-coding regions. The mice contained variable numbers of copies of the gene and, with only one exception, the mice with the highest growth rate had the most copies of the gene. The mice were fed zinc to induce transcription of the fusion gene but this may not have been necessary. Most of the mice containing the gene were larger than normal before being fed zinc, and one animal which was removed from the zinc diet continued to grow at an accelerated rate. In mice with the highest copy number of the gene the level of growth hormone production was between 100 and 800 times the normal level. The serum concentration in one of the mice actually exceeded 100 $\mu g\ ml^{-1}$.

Thus, aside from the variability of expression in second generation mice and the lack of response to glucocorticoids, results with the metallothionein promoter are highly encouraging. Sadly for the developmental biologist, however, this is not the case for globin genes. Although transcripts have been detected in muscle tissue from one mouse line carrying the rabbit β-globin gene, neither the rabbit β-globin gene, nor a fusion gene containing the 5′ half of the mouse β-globin gene and the 3′ half of a human β-globin gene are expressed in the blood cells of seven mouse lines carrying the rabbit gene and two lines carrying the fusion gene (Frank Constantini and Elizabeth Lacy, personal communication). This difference in behaviour of the β-globin genes and the metallothionein gene in transgenic mice may be a reflection of a fundamental difference between the two genes. Globin genes are expressed only in cells of the erythroid lineage and only at a specific stage in development. While expression of the metallothionein-1 gene varies from tissue to tissue, most tissues express the gene at some level. Thus metallothionein might almost be regarded as a housekeeping gene which displays tissue specific variation in the extent of expression. This in no way detracts from the usefulness of this promoter in obtaining high levels of expression of any gene to which it is suitably fused, and this is powerfully demonstrated by the growth hormone study.

The authors discuss a number of implications of their results. The elevation of serum protein levels by these means could provide a way of studying hormone action a way of accelerating animal growth, a method of producing valuable gene products and a means of correcting genetic disease. Before considering these last three applications individually there is one point which should be made. They all rely to a greater or lesser extent on the transmission through the germ line of the ability to express the gene. However, the metallothionein-1 thymidine kinase fusion gene was sometimes not expressed in the offspring of mice which were themselves expressing the gene. If the metallothionein-growth hormone fusion gene behaves similarly this phenomenon will require further investigation.

The benefits which might accrue from a shorter production time seem a sufficient spur to ensure that fusion genes of this kind will be used to accelerate the growth of livestock animals. Also, the novel concept of genetic farming — the use of animals to produce large amounts of commercially important proteins — may be applied to the production of proteins which require secondary modifications not correctly made in yeast or other eukaryotic host cells. Finally, this achievement once again brings into question the potential of this technology as a means of correcting genetic disease. It will have become clear that such an approach will only be applicable where a genetic disorder may be prevented by simply elevating the serum concentration of a particular protein. In order to correct a genetic disorder such as a thalassemia by manipulation of the embryo, expression of the introduced gene would probably have to be limited to cells of the erythroid lineage and this is not at present achievable. Also, for reasons which have been presented in a recent review in this journal (Williamson, R. *Nature* **298**, 416; 1982) it seems exceedingly unlikely that there will ever be a clinical requirement for such therapy to be applied to the embryo. Control sequences such as the metallothionein promoter may, however, prove useful in developing methods of correcting gene disorders in the somatic cells of affected patients.

Hypertension and inhibition of the sodium pump: a strong link but in which chain?

from Ian M. Glynn and T. J. Rink

THE experiments reported in this issue of *Nature* (p.650) by Hamlyn and his colleagues[1] from Baltimore, showing that the blood from patients with high blood pressure contains an inhibitor of $(Na^+ + K^+)$ATPase, are welcome for their cogency. Similar claims have been made before[2,3]; but always on the basis of evidence too indirect to be wholly convincing in a field where direct testing is feasible. The direct test has now been made and, though the effects are small, the answer seems clear. The blood plasma of patients with essential hypertension, that is, with a permanently raised arterial blood pressure not secondary to any known cause, is more effective at inhibiting a partially purified $(Na^+ + K^+)$ ATPase (the enzyme that pumps sodium ions across cell membranes in exchange for potassium ions) from dog kidney than is plasma from normal subjects; and the higher the blood pressure the more inhibitory the plasma tends to be. Furthermore, since plasma from most normal subjects is slightly inhibitory, the inhibitor may be of physiological as well as pathological interest.

The crucial question is whether correlation implies causation: does the inhibitor have a role in the aetiology of essential hypertension, and, if it has, what is that role?

There is no doubt that the new results fit well with the notion that essential hypertension is a disease in which the inability of the kidneys to cope normally with salt and water loads is compensated for, not only by a rise in blood pressure[4–6], but also by an increase in the plasma concentration of a (hypothetical) hormone that promotes salt and water excretion by inhibiting sodium reabsorption in the kidney tubules[7–9]. The circulating $(Na^+ + K^+)$ATPase inhibitor could well serve as the hypothetical hormone, though there is so far no evidence that it does in fact inhibit sodium reabsorption in the kidney tubules or that it has a natriuretic (promoting salt excretion) effect.

The results also fit well with the hypothesis that the narrowing of the arterioles — which everyone agrees is the immediate cause of the raised arterial blood pressure in established essential hypertension — represents a secondary effect of the increased level of the hypothetical sodium-transport-inhibiting hormone. The suggestion is that inhibition of the membrane sodium pump in the arteriolar smooth muscle cells leads to a rise in intracellular sodium concentration, which, by the action of a Na^+-Ca^{2+} exchange mechanism, increases intracellular calcium concentration and hence contractility[10].

Attractive though this hypothesis may be, it is still only a hypothesis. There is evidence that inhibition of the sodium pump in smooth muscle, by a reduction in extracellular potassium or by high concentrations of cardiac glycosides, can lead to an increase in arteriolar resistance in the rat[11], but it is not clear that the circulating inhibitor reported by Hamlyn *et al.* would have a similar effect, or, if it had, that the effect would be maintained. It is perhaps ominous that an almost identical hypothesis[12,13] proposed in the late 1960s to explain the ability of cardiac glycosides to increase the force of contraction of the heart still remains controversial. And though it is comforting to have a plausible hormonal explanation of the paradox that salt and water retention can lead to hypertension associated with a normal cardiac output and increased arteriolar resistance, the explanation proposed may not be sufficient or even correct. The consensus of opinion seems to be that in patients with coarctation of the aorta (a pathological narrowing of the aorta above the level of the renal arteries), the arterial blood pressure is high in regions above the coarctation and roughly normal in regions below it — in other words the pressure is adjusted to suit the kidneys — yet the blood flow through the arterioles is normal in both regions[4,6,14]. This implies that the calibre of the arterioles is reduced in the upper half of the body but not in the lower, a fact that is not easily explained if the reduced calibre of the arterioles is caused by the action of a circulating agent on the smooth muscle of their walls.

Strong evidence that a circulating agent can be involved in the genesis of hypertension comes from experiments in which rats of different strains had their skin and subcutaneous tissue joined so that substances could exchange between the bloodstreams. When rats from a strain that develop hypertension on a high-salt diet had their circulation linked to rats that did not respond in this way, the originally unresponsive rats rapidly developed hypertension when fed salt[15]. These experiments have been interpreted to suggest that the salt-sensitive rat on a high-salt diet produces a circulating natriuretic hormone which increases the contractility of the smooth muscle of the arterioles[9]. That is not the only possible interpretation, however; it is at least as likely that the effect of the transferred circulating factor is to make the kidney of the originally salt-resistant rat less able to excrete salt and water, and that the hypertension arises secondarily. It would be interesting to see whether plasma from the salt-fed, salt-sensitive rat behaves like plasma from hypertensive patients in inhibiting $(Na^+ + K^+)$ATPase.

Other questions that must now be asked concern the relation between the $(Na^+ + K^+)$ATPase inhibitor demonstrated by Hamlyn *et al.* and (1) the substances present in the plasma of hypertensive patients that can increase the vascular reactivity of rats to noradrenaline and angiotensin[16], (2) the high- and low-molecular weight natriuretic substances that have been extracted from the urine of salt-loaded subjects[17], (3) the natriuretic substance found in the urine of normal men immersed up to the neck in water at 34.5°C (ref. 18), and (4) the natriuretic and $(Na^+ + K^+)$ATPase-inhibiting substance found in the plasma of volume-expanded rats[19]. It will also be necessary to consider to what extent the presence of circulating $(Na^+ + K^+)$ATPase inhibitor can explain the numerous and sometimes contradictory reports of abnormalities in sodium, potassium and lithium transport in the red blood cells and white blood cells of patients with hypertension and of their relatives with normal blood pressure.

Presumably the first priority of the group at Baltimore will be to characterize their inhibitor. They have already shown that it is heat-stable, that it does not cross-react with antisera to cardiac glycosides and that it acts rapidly even at concentrations at which the maximal effect is small. It should not be difficult to gain a rough idea of its molecular weight, or to determine whether or not it is organic. More precise identification will be more difficult, but it must be an advantage that the assay is so simple. When the inhibitor is identified and can be prepared in quantity, it should be possible to determine whether it can produce a maintained narrowing of

arterioles, whether it can promote salt excretion by the kidney and whether the kidneys of hypertensive animals or patients are less sensitive to it than are the kidneys of normal animals or patients. The answers to these questions should define the role of the inhibitor in the aetiology of hypertension — if indeed it has one. □

The prehistoric salt trade in Europe

from John Alexander

SUFFICIENT archaeological evidence has now accumulated for a picture of the winning and trading of common salt in prehistoric Europe to emerge. North of the Alps several big inland deposits were exploited and traded over long distances in the years before 500 BC. In the Mediterrean coastlands sea-salt was used, but further north, where boiling was necessary, this was not at first common. After 500 BC the inland suppliers disappeared and production moved to the coasts, perhaps as a result of the changes brought about by the mass migration of peoples at that time.

Common salt is not just a luxury for human communities with largely cereal diets, but is an essential. The salt received from flesh, blood and urine is insufficient for dietary needs. Salt may also be required for preserving flesh (including fish) and hides, or for religious purposes. Since substantial deposits of salt are rare in Europe and many regions are remote from seashores, salt was traded over long distances, as is known from the earliest written records (the last few centuries BC). Detailed knowledge of the industry in earlier prehistoric times has always been difficult to come by since the traded salt does not survive, but much recent excavation at the production centres makes it possible to find out when they were exploited, whilst a study of traded metal objects suggests the routes used for salt-trading[1].

Common salt is obtainable in quantity from four kinds of source — sea-salt, rock salt, saline springs and salt-rich plants — all of which were present and utilized in Europe. Sea (or bay) salt is only won with ease on flat coasts where advantage can be taken of tidal variation. In the Mediterranean coastlands the work is relatively easy as solar heat is sufficient to evaporate the brine. Elsewhere boiling is essential and the collection of fuel and the making of vessels are major additions to the work. The debris from the boiling process (broken vessels, burnt earth and charcoal) can be recognized and dated, as in the 'red hills' of Essex.

Rock (or haline) salt can only be obtained in quantity by mining, but needs little further processing. In the few localities where mining occurred, as in central Austria, shafts and galleries dug along the seams have been found and dated.

Brine from inland saline springs, or from the salt-impregnated earth around them (from which the salt must be dissolved and cleansed before boiling) will leave debris similar to the seaside boiling-sites and can, as in the Saale Basin in Germany, be recognized and dated.

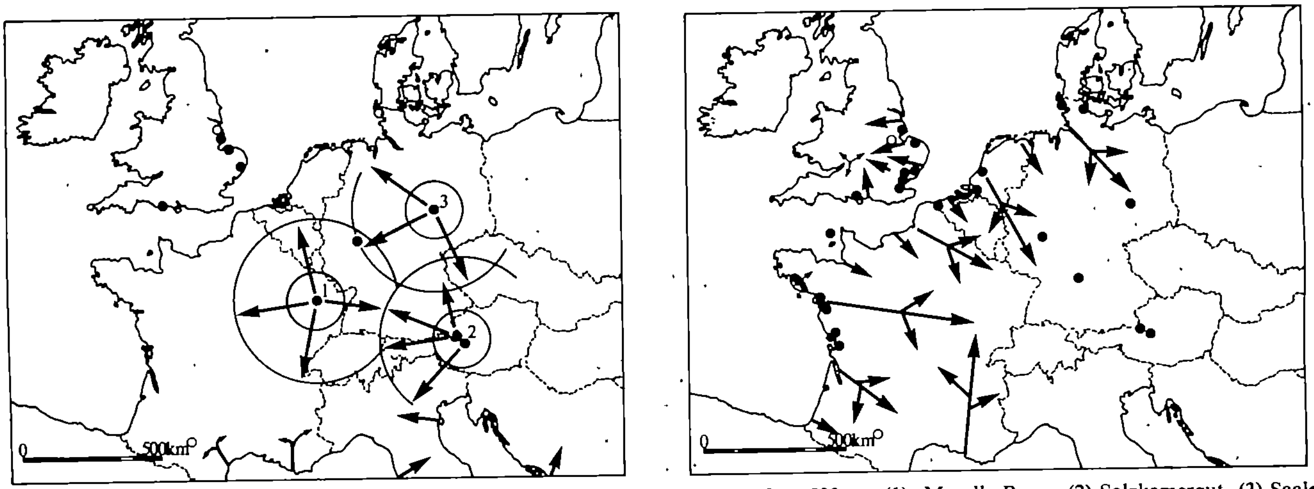
Salt-rich plants can be burnt and their salt dissolved and evaporated by boiling. Tacitus reported the existence of the industry from Germany in the first century AD but it has not yet been recognized archaeologically although it would have left debris.

Before 500 BC coastal working of salt in regions where boiling was necessary (the Atlantic and North Seaboards) was rare[2,3] and only around the Mediterranean Sea, where solar heat was sufficient to evaporate the brine, does sea-salt seem to have been important[4]. Routes inland, such as the 'Via Salaria' in Tuscany (from near Ostia to the Sabine Hills), existed from at least the fifth century BC, but there is no evidence that sea-salt was carried up into central Europe.

North of the Alps, some inland sources of salt were used in the early part of the first millennium, as they had been in the second millennium, and the three areas with major reserves of salt, shown in the map below left, were increasingly exploited. Estimates of salt production show that it was in excess of local needs and that wide regions were being supplied[3,5].

In Austria, where names like HALLstatt and HALLein-Dürnberg preserve references to salt, thick veins of common salt were followed down for more than 400 m by skillfully constructed shafts and galleries. These, similar to contemporary Alpine coppermines, must have been the work of experienced miners[6,7]. They were especially active between 1000 and 400 BC when the 'eastern workings' produced thousands of kilogrammes of salt in heart-shaped slabs weighing up to 40 kg each. Nearby contemporary cemeteries are very rich in metal objects, especially jewellery, of types found within 200 km of the production sites and may well reflect the wealth resulting from a long-distance trade in salt slabs. The highly skilled miners appear to have worked only in the summer in the high, isolated alpine valleys at Hallstatt, and caravans of pack animals or porters would have been necessary to carry away the slabs. The mines appear to have gone out of use after 400 BC. A distant analogy with the Saharan fourteenth to sixteenth century AD saltmines at Taghaza,

John Alexander is in the Department of Archaeology, University of Cambridge, Downing Street, Cambridge CB2 3DZ.



The suggested pattern of (left) salt production in western and central Europe before 500 BC: (1) Moselle Basin, (2) Salzkamergut, (3) Saale Basin; and (right) after 500 BC (after ref. 2).

0028-0836/82/500577-02$01 00

where the slabs were carried over 1,000 km by regular caravans, is interesting[8,9].

At the same time a different kind of large-scale exploitation was being practised in the Saale Basin in Saxony. Here around HALLe, salt springs over some 200 km^2 were exploited. The brine was boiled in batteries of distinctive pottery vessels and mounds of debris five metres high have been found. As in Austria, there is an absence of remains after 400 BC, suggesting that production ceased for some centuries[10,11]. Very large numbers of conical lumps of hard salt weighing several kilogrammes were produced and were probably dispersed over a wide area, perhaps several thousand square kilometres. The mechanism for production and dispersal may well have differed from that in Austria, since no great expertise would have been necessary, although the labour required suggests considerable organization. A distant analogy may be seen in the brine springs at Uvinza in Tanzania which are scattered over 30 km^2 and were worked seasonally by up to 20,000 people in the nineteenth century AD[12].

A third centre, worked on a similarly large scale in the same centuries, lay in eastern France among the brine springs of the Moselle valley near Seille. Here, over some 200 hectares, debris from brine boiling in great banks up to 17 m high are found. Once again production seems to have stopped after 400 BC. Production on this scale suggests that the salt served the needs of a wide area[13,14].

No other inland centres as large as these three have been found and it seems likely, in the absence of extensive coastal salt-boilings, that they supplied most of the North European Plain with salt (see map on left). Long-distance trading, as in Africa, was accompanied by trade in more durable, especially metal, objects[20].

A major change in salt production seems to have taken place after 400 BC. Large-scale working at inland centres stopped while the number of coastal brine-boiling sites greatly increased. The new sites appeared on the Atlantic coasts of France[15,16], Belgium[19] and southern England[17] in numbers too great merely to satisfy the needs of coastal communities (see map on bottom right of p.577). There was probably a salt-trade inland, by boat up the rivers, since there are many boiling-sites near estuaries. Trading of this kind penetrated some 300 km into the hinterland of West Africa in the nineteenth century AD[18].

That there was some connection between the decline of the inland centres and the rise of the coastal ones in the fourth to second centuries BC seems likely, but what brought about the change is not yet clear. Those centuries saw great changes in central Europe, with the migration of large numbers of Celtic-speaking peoples into Italy and the Balkans and the development of the La Tène culture. These may well have interrupted patterns of control and trade and been coupled with the exhaustion of supplies of firewood and the need for deep, easily flooded mines. Coastal production in areas with greater resources of firewood and with less opportunity for centralized controls may have taken advantage of this.

Ball lightning wild and wonderful

from Martin A. Uman

BURBIDGE and Robertson report in this issue of *Nature* (p.623) the unusual observation of a liquid-like 'blob' entering a house under a door and moving along the floor immediately after lightning struck extremely close by. Because of the association with lightning, it is tempting to classify the 'blob' as ball lightning, although it represents an extremum in the spectrum of observations of that phenomenon for it had a very low luminosity, lacked a well defined shape and was not free-floating.

Reports of ball lightning can be found in both ancient and modern literature and the similarity in described size, colour, smell, duration, sound at demise and physical damage lends overwhelming support to the view that ball lightning is a real phenomenon (rather than a visual after-image or a psychological aberration). Nevertheless, no adequate laboratory simulation of ball lightning has been achieved, although similar phenomena are occasionally generated by accident in high-current electric machinery.

Most ball lightnings are spherical or oval, between the size of a marble and a basketball, exhibit a faint glow and last a few seconds. They appear to float while moving horizontally and can occur inside houses and all-metal airplanes as well as out-of-doors. There may well be more than one kind of ball lightning. For example, the bright spheres which hang high in the air and are seen at considerable distances would seem different from the typical ball lightning described above. On the other hand, these very bright, relatively long-lasting and apparently large balls could represent the upper end of a scale of phenomena in which the 'blob' or 'flow of light' seen by the New Zealand observers, with its low luminosity, lack of well defined shape and location at ground level, could represent the bottom.

While Burbidge and Robertson's observations are of considerable interest, the idea they put forward to explain the motion of the blob — the existence of free magnetic dipoles or permanent current loops in the blob that interact with the magnetic field gradient — would appear farfetched. How could a current loop exist for 15 seconds in a liquid or gas near ambient temperature and pressure? What available liquid or gaseous material could have permanent magnetic dipoles? It is, nevertheless, interesting to put numbers in equation (2) in Burbidge and Robertson's paper. With the horizontal gradients in the vertical field given in Fig. 1 a horizontal force of about 10^{-5} Newtons will be produced by an assumed current of 10 A flowing around the perimeter of the blob. The blob must be slightly more dense than air. If it were less, it would rise. If it were much more, it would appear more like a 'puddle' than a 'blob'. The drag force of the ambient air on such a blob, for the observed velocity of 0.25 m s^{-1}, is about the same as the magnetic force for the assumed 10 A current. Thus, for that value of current, the two forces balance to yield the observed blob velocity. If the vertical gradient in the horizontal field were such as to produce a vertically upward magnetic force of about the same magnitude as the horizontal force, the blob would be levitated if its density were less than 1 per cent greater than air. Otherwise, the magnetic force would be less than the gravitational force, and the blob would remain on the ground. It is worth noting that a 10 A current flowing in an air arc or in an air arc contaminated by vapours of solids produces a level of light output that is painful to look at.

Finally, we should address the question of just what is a ball lightning. There is no consensus! *Nature* is probably the primary publication source for unconventional (if there are truly conventional) ball lightning

Martin A. Uman is in the Department of Electrical Engineering, University of Florida, Gainesville, Florida 32611.

observations and theories. Many of these theories are improbable but do make for interesting reading. A few examples follow. Wooding (Laser Analogue to Ball Lightning, *Nature* **239**, 934; 1972) would have the lightning act as a laser to produce a high-power optical pulse which would ablate a solid surface producing a plasma vortex ring (the ball). The laser radiation would escape at points along the lightning channel when it zigged or zagged. Altschuler, House and Hildner (Is Ball Lightning a Nuclear Phenomenon? *Nature* **228**, 545; 1970) suggest that high-energy protons from lightning collide with air molecules and cause nuclear reactions which produce a high-energy ball. They do note, however, that being near such balls could result in radiation sickness or worse. Ashby and Whitehead (Is Ball Lightning Caused by Antimatter Meteorites? *Nature* **230**, 180; 1971) report the observation of photons at the energy corresponding to position annihilation, and suggest micrometre-size antimatter meteorites as the source for ball lightning. Crawford (Antimatter and Ball Lightning, *Nature* **239**, 395; 1972) has interpreted the measurements of Ashby and Whitehead to suggest that ball lightning is due to the photons produced when positrons in cosmic ray showers (EAS) come to rest and are annihilated.

Ball lightning is a wild and wonderful subject for study. The interested reader can best be introduced to the available theories and experimental data by reading the book by J.D. Barry *Ball Lightning and Bead Lightning* Plenum Press, New York, 1980). ☐

Vive le replicon!

from Ron Laskey and Marcel Mechali

TWENTY years ago Jacob, Brenner and Cuzin[1,2] proposed a fundamental unit of DNA replication, the replicon. They argued that tight coupling of DNA replication to other cellular events was regulated by the action of a diffusible positive factor, 'the initiator', on a specialized chromosomal region, 'the replicator'; resulting in replication of the entire circular chromosome of a bacterium, plasmid or bacteriophage. The twentieth anniversary of the replicon hypothesis was celebrated by a meeting* which considered its impact on current studies of prokaryotic and eukaryotic DNA replication.

The chromosomal replicator of *Escherichia coli* has been mapped to within a 245 base pair (bp) fragment from the *oriC* region. This is sufficient to direct initiation of replication *in vitro*. Surprisingly, polymerization does not begin in this fragment itself but in the upstream flanking DNA, irrespective of the nucleotide sequence of the flanking region (Hirota, National Institute of Genetics, Japan). Replication subsequently becomes bidirectional after an asymmetric start.

The product of gene *dnaA* behaves as an initiator for the chromosomal replicon of *E.coli* and a cell-free system from *E.coli* requires the dnaA protein for initiation at *oriC* (J. Kaguni, Stanford Medical School). Fractionation of this system has produced an intriguing result. As well as several identified components[3] and at least two unidentified positive factors, an additional template-specificity factor is required for initiation at the *E.coli* replication origin. In the absence of this factor the amount of DNA synthesis increases, but synthesis no longer requires the *dnaA* gene product and it is no longer template specific for *oriC*. Apparently the enzymes of replication could initiate elsewhere and the replicon concept has acquired another component which constrains initiation to the site specified by the initiator.

In the initiation of DNA replication two discrete roles for RNA synthesis have been identified. First, DNA chains are usually primed by synthesis of oligoribonucleotide primers[4]. Second, there are several examples of transcriptional activation of DNA replication in which the origin region is transcribed to form a transcript which allows a true priming event subsequently to occur. A particularly good example is phage λ where a pause during transcription through the origin appears to expose the site for priming in a single-stranded form (Hobom, Albert Ludwigs University, Freiburg). Alternatively, in the replication of plasmid Col E1, interaction of the long RNA primer with a complementary transcript from the opposite strand controls plasmid copy number (Tomizawa, NIH). In phage T7, two promoters for T7 RNA polymerase flank the primary replication origin and appear to be involved in replication initiation. They have no open reading frame between them and their deletion inhibits replication from that origin (Richardson, Harvard Medical School). Conversely, deletion of the primary replication origin results in initiation at alternative sites which are also near promoters for T7 RNA polymerase. During elongation nascent T7 DNA chains are primed by the T7 gene 4 protein which could use its associated helicase activity to unwind DNA, thus exposing primase sites (Richardson). In T4 the virus-coded primase and helicase are different proteins which interact during replication (Alberts, UCSF Medical School).

Studies of replication in eukaryotes have lagged far behind, but promising experimental systems are now emerging for studying several aspects of the process including RNA priming. Thus Conaway (Stanford Medical School) reported that the primase activity from *Drosophila* co-purifies with DNA polymerase α, the polymerase primarily responsible for replication in eukaryotes.

A clear exception to the rule of RNA priming is provided by adenovirus, and a controversy has existed over whether the DNA polymerase which replicates adenovirus DNA is α or γ. This appears to have been resolved by the finding that it is a separate polymerase encoded by the virus itself (Hurwitz, Albert Einstein College, New York). The polymerase is complexed with the 'pre-terminal protein' which binds dCTP and then attaches covalently to the ends of the linear genome during priming. In the presence of the virus-encoded DNA-binding protein and two other factors, full-length copies of the adeno genome can be synthesized *in vitro* from purified components.

Recent studies in yeast may advance our knowledge of eukaryotic replicons. Transformation assays have identified a limited subset of DNA segments which allow plasmids to replicate autonomously in yeast. These autonomously replicating sequences have the properties expected of chromosomal 'replicators'. Therefore evidence that replication initiates at these sequences is important and Campbell (CalTech) described a cell-free system which appears to initiate preferentially at autonomously replicating sequences *in vitro*. An additional advantage of yeast is the advanced state of yeast genetics and a permeabilized cell system derived from a thermosensitive cell-cycle mutant (cdc8) which can be complemented by fractionated extracts from wild type (Campbell). The transformation assay also led to the isolation of yeast centromere sequences which confer mitotic and meiotic stability on plasmids replicating in yeast. Carbon (University of California, Santa Barbara) reported another effect of the centromere — control of copy number of the endogenous 2μ plasmid of yeast. When a centromere is introduced, the copy number falls from around 50 to only 1 per cell.

Yeast has advantages over higher eukaryotes for the study of replication but Hamlin (University of Virginia Medical School) described a promising approach for studying a replicon in Chinese hamster ovary cells. The gene coding for dihydrofolate reductase becomes amplified in response to methotrexate selection. The degree of amplification

allows restriction fragments from this gene and its flanking sequences to be recognized in digests of total DNA. Pulse-labelling with thymidine reveals that the characteristic restriction fragments replicate early in the S phase of the cell cycle and that there is a temporal order of fragment labelling. Isolation of these fragments and insertion into other cells could help in elucidating the nature of the elusive eukaryotic 'replicon'.

Is polypeptide heterogeneity the key to neurofilament function?

from Rosaleen Calvert

THE most enigmatic component of the cytoskeleton remains the intermediate filament. Microtubules and microfilaments can depolymerize to tubulin and to actin respectively, and the effects of their absence in the cell investigated. In contrast, there are no situations where intermediate filaments depolymerize *in vivo* (though other ultrastructural changes do occur) and no known drugs which have this effect. Nonetheless, by using a variety of approaches we are now beginning to find out what the functions of these filaments may be. One class of intermediate filaments — the neurofilaments — is the subject of this article (see also refs 1,2).

Intermediate filaments were first defined ultrastructurally as filaments intermediate in width between the thick filaments of myosin and thin filaments of actin[3]. Subsequent purification from different tissues led to the surprising observation that although the proteins actin and tubulin always consisted of one and two polypeptides respectively, there were five classes of intermediate filaments. In the case of the epithelial cytokeratins, they contain at least nineteen different polypeptides in contrast to, for instance, the fibroblast intermediate filament protein vimentin which is a single gene product. The three remaining intermediate filaments are desmin in muscle, glial fibrillary acidic protein in glia and neurofilaments. Mammalian neurofilaments consist of only three polypeptides of molecular weight about 200,000, 150,000 and 70,000 (ref.4); these will subsequently be referred to as the 200K, 150K and 70K. It has proved fruitful to probe their different roles in neuronal structure and behaviour.

The first indication of heterogeneity in neurofilament structure came from a genetic polymorphism of the 200K in rabbits, in which one variety had a molecular weight about 10,000 larger than the other. Heterozygotes and homozygotes for each allele were observed. Unfortunately, no functional attributes of these animals mirror their molecular differences[5]. There is further heterogeneity in the isoelectric points of all three polypeptides[6], but again, the functional significance is not yet clear.

Recently, immunofluorescence has revealed neuronal processes which lack or have very little of the highest-molecular-weight polypeptide — the dendrites of pyramidal cells of the cerebral cortex and hippocampus and certain cell bodies or axons in the brain stem on sections of adult rat[7] and human[8] brain, and certain dorsal root ganglion[9,10] neurones. In developing rat brain the 200K can be first detected with Coomassie brilliant blue stain on a gel three days postnatum, whereas the 150K and 70K can be seen one day prenatum. It could be therefore that the 200K is found only in mature axons[11]. However neurofilaments are known to be susceptible to an endogenous calcium protease and there is some evidence that this is not evenly distributed, at least within single neurones[12], so it is possible that the 200K is proteolysed during tissue preparation.

Ten nm filaments can be reconstituted from the 70K alone[13-15] or with the 200K added, and thin sections show projecting side arms[13], suggesting that the 200K could be responsible for the bridges between neurofilaments observed in the electron microscope. There is some immunological evidence for this: antibodies specific for the 200K appear to label the cross-links between neurofilaments in electron microscope studies of whole neuronal cytoskeletons[16]. Moreover, *in vitro* digestion studies using trypsin have shown that 75 per cent of both the 200K and the 150K can be removed, leaving morphologically intact filaments[17].

It is interesting that in the growing axon, the neurofilament triplet is transported distally at eight times the final rate. Retardation correlates with the increasing quantities of the 200K which appear at this time, and it has been proposed that a concomitant formation of cross-bridges could be the explanation for the change in rate of axoplasmic transport[18]. This anterograde transport of neurofilament polypeptides also raises the question of what happens to the filaments or networks of filaments when they reach the axon terminal. Soluble subunits have never been found, so degradation is still considered as the most plausible mechanism for their disposal[19]. In support of this mechanism is the observation that a monoclonal antibody[20,21], which binds strongly to the 200K and weakly to the 150K, binds to these and only two other polypeptides in neonatal rat brain whereas in the course of further development a whole ladder of antibody-binding polypeptides appears below the 200K on polyacrylamide gels. A possible interpretation of this observation is that gradual cessation of axonal outgrowth necessitates an increase in degradative processes to dispose of neurofilaments accumulating at the axonal terminals. The 200K polypeptide thus emerges with a distinct structural role. Further compari-

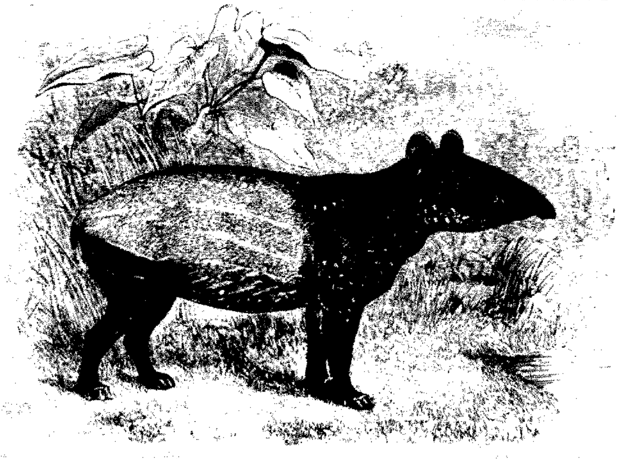
NEW OR RARE ANIMALS IN THE ZOOLOGICAL SOCIETY



THE MALAYAN TAPIR (*Tapirus indicus*). There is no better instance of discontinuous distribution on the world's surface than that of the Tapirs. While Tropical America contains several species of *Tapirus*, and may be regarded as the *focus* of the genus, a single well-marked species occurs in Tropical Asia. This is the Malayan or Indian Tapir, *Tapirus indicus* (sive *malayanus*) of systematists. From *Nature* **27**, 151, 14 December 1882.

0028-0836/82/500580-02$01.00

son of the situations in which it is present or absent may provide more insight into its function.

Special features of the other two neurofilament polypeptides are scarce. In a study of polypeptide compositions of different sections of the axons in a mouse optic tract, the 150K exhibited microheterogeneity. Two major species were visible along the length of the optic pathway with an extra one appearing distally. The amount of this third polypeptide could be increased by incubation of the intact optic pathway *in vitro* with a calcium-containing buffer, suggesting the presence of a protease which was absent or inactive in the proximal part of the axons[12]. This again supports the idea that neurofilaments are degraded as they reach the axon terminal.

The anti-neurofilament monoclonal antibody[20] mentioned above also binds to a high-molecular-weight polypeptide present in developing rat brain and absent in other tissues of neonatal rat. Thus by immunological criteria there seems to be another neurofilament polypeptide associated with immature brain[21]. Whether other properties of this polypeptide, such as solubility and secondary structure, will confirm its assignment as an intermediate filament protein remains to be seen.

An interesting selection of rather different neurofilament structures is now accumulating. Those situations where a change in structure can be seen and correlated with a physiological event offer the best chances of using structural differences to throw light on the elusive neurofilament function. □

Collagen genes

from Paul Tolstoshev and Ellen Solomon

THE collagen genes, a major family of at least fifteen genes found throughout the vertebrate and invertebrate kingdoms, have been much studied, not only for what they can tell us about the molecular biology of evolution but also because they are developmentally regulated, crucial for the structural integrity of most tissues and are implicated in many human mendelian genetic disorders. Reports delivered at a recent meeting* revealed progress in understanding of all these areas.

All collagenous proteins have in common a triple-helical region with a repeating pattern in which every third amino acid is glycine. The interstitial collagens (types I, II and III) form rigid rod-like structures while basement membrane collagen (type IV) forms a different kind of molecule, still with large amounts of triple helix, but with nonhelical interruptions.

A very detailed picture of the gene for the α_2 chain of type I collagen[1-3] is now available (H. Boedtker, Harvard University). The most remarkable feature of this gene, apart from its size and that it contains about 50 introns in 40 kilobases (kb) of DNA, is the unique conservation of the 54 base pair (bp) exon size throughout the α-chain-coding region. There has been much speculation as to the significance of this structure in the evolution of collagen genes[4,5] and the analysis of other collagen genes has been awaited with great interest. Information is now available for mouse α_1 (I) (ref. 6), chick α_1 (II) (B. Upholt, University of Chicago), chick α_1 (III) (Y. Yamada, NCI, Bethesda), human α_2 (I) (F. Ramirez, Rutgers University) and an α_1 (I)-like gene[7]. All these genes have conserved the basic 54 bp (18 amino acid) exon size in the triple-helical coding region of the gene. The size of this exon and its variations [45 bp (54 − 9), 108 (54 × 2) and 99 (108 − 9)] are similar to those found in the chick α_2 (I) collagen gene. The only permissible deletions thus appear to be of size 9 bp — one Gly-X-Y triplet. Comparison of particular exons among the different genes indicates that sizes and position are also strongly conserved. Intron sizes, however, vary enormously, from less than 100 bp to several thousand. In general the data are compatible with the idea that the genes had their origin in an ancestral 54 bp sequence which expanded by repeated duplications, but was constrained by the absolute necessity of maintaining the repeating Gly-X-Y structure in the protein.

Another remarkable feature of the evolution of the collagen genes is the way that the amino acid sequence and nucleotide sequence have been conserved around the carbohydrate attachment site in the C-terminal propeptide region in chick α_2 (I) and human α_2 (I) (D. Prockop; Rutgers University). Similar conservation in this region has been observed in the sheep α_2 (I) gene[7], the chick α_1 (II) gene (B. Olsen, Rutgers University) and the chick α_1 (III) gene. It is easy to think of functional reasons why such conservation occurs at the amino acid level but lack of third-position codon change in this region is striking, implying selection at the nucleotide level for the conservation of the sequence and making the region a fascinating one to explore — it may perhaps function as the attachment site for a regulatory molecule.

Do all collagen genes have the same basic structural features and have a common evolutionary history? From recent studies on the structures of fruitfly[9,10] and nematode[11] collagen genes, the answer to at least the first question is clearly no. The cuticle nematode *C. elegans* contains a large number of collagenase-sensitive cuticle proteins, and the genes for two of these have been isolated (D. Hirsch, University of Colorado). These two genes are not closely linked, are related but not identical and are each about 1,200 bp long. Sequences coding for Gly-X-Y repeats are seen in both of the genes, but none of the exons is 54 bp or variants thereof, or a multiple of 9 bp. In fact, the first gene is divided into only three exons, the second into two. Analysis of a fragment of a *Drosophila* collagen gene (J. Monson, University of California, San Francisco) has revealed two large regions, of 662 and 726 bp, which encode a region of 460 amino acids. The structure of this gene is again quite different from that of the vertebrate interstitial collagen genes. The *Drosophila* collagen protein appears to be closely related to basement membrane type IV collagen (J. Fessler, University of California, Los Angeles) and cross-reacts with antibodies to mouse type IV collagen. The big question now is: what is the structure of the genes for vertebrate basement membrane collagens — are they similar to the interstitial collagen genes or like that of the nematode and *Drosophila?* The answer obviously is crucial to our understanding of the evolution of collagen genes.

Analyses using dot hybridization on genomic human placental DNA (R. Dalgleish, NHLBI, Bethsda) indicate that

there is only one copy of each of the α_1 (I), α_2 (I) and α_1 (I)-like genes per haploid genome in humans. The genes coding for the two chains of human type I collagen are located on different human chromosomes[12,13] α_2 (I) on chromosome 7 and α_1 (I) on chromosome 17 (E. Solomon, ICRF, London; F. Ramirez). The presence of the genes for the different chains of heteropolymer on different chromosomes has many well known precedents, and does not allow prediction of whether other related genes will be clustered near either gene.

One of the most studied systems of collagen gene regulation has been the Rous sarcoma virus (RSV)-transformed chick embryo fibroblast (CEF) where the production of type I collagen is dramatically decreased on transformation, probably by regulation at the transcriptional level[14,15]. The availability of temperature-sensitive strains of the virus has allowed analysis of both the induction and reversal of the transformed state (M. Sobel, NIDR, Bethesda) and has prompted studies of the transcriptional regulatory signals of the chick α_2 (I) collagen gene. The promoter of this gene has been inserted into a hybrid SV40/pBR322 shuttle vector (B. de Crombrugghe, NCI, Bethesda) which makes possible detection of promoter activity by measurement of the activity of the product of the *Escherichia coli* chloramphenicol acetyl transferase gene. Analysis of deletion mutants in the α_2 (I) collagen promoter region of this vector has provided some evidence for regulatory sequences, particularly those potentially capable of forming hairpin structures[16]. Neither this approach, nor attempts to correlate methylation of the α_2 collagen gene with its activity[17] (C. McKeon, NCI, Bethesda), have been successful in yielding clues to the precise nature of transcriptional regulatory mechanisms. However, a role for methylation in the reduction of activity of type I procollagen gene expression on transformation of human lung fibroblasts with SV40 has recently been reported[18].

Chick embryo chondroblasts, which normally produce type II collagen, when transformed with RSV strain show decreased synthesis of type II collagen and decreased levels of type II collagen mRNA (ref. 19 and S. Adams, University of Philadelphia). Surprisingly, type I collagen mRNA begins to accumulate, but is not used by the cells to make type I collagen. This is clearly a regulation at the level of translation. Other examples of translational regulation are seen in the effects of the N-terminal propeptides on collagen synthesis in normal and dermatosporatic sheep fibroblasts (P. Müller, Max Plank Institut, Munich) and in the regulation of collagen gene expression in fetal sheep skin development[20] and human lung fibroblasts[21]. Clearly, continued analysis of these and other systems using cloned probes will reveal the exact details of the variety of mechanisms cells use to modulate their collagen production.

A variety of human genetic disorders may be due to a structural defect of collagen. These include Ostrogenesis imperfecta, several of the Ehlers-Danlos syndromes and the Marfans syndrome. These disorders, while normally inherited in simple mendelian fashion, vary greatly in the severity of their clinical symptons. Biosynthetic studies of collagen production in cultured fibroblasts from affected individuals show abnormal secretion of collagen in all the three types of disease (P. Byers, University of Washington). The abnormality may be due to underproduction or lack of one constituent α chain, an abnormally long or short chain causing incorrect assembly of the precursor, or inefficient cleavage of the terminal peptides. The wide variability of symptoms has long caused difficulties of classifications of heritable disorders of connective tissue and of meaningful genetic counselling. Classification using biochemical methods is being attempted (D. Rowe, University of Connecticut), but DNA analysis is obviously of prime importance in the understanding of these disorders. Such analyses for two individual cases were reported. A fibroblast culture from an affected individual with the severe perinatal lethal form of OI type II demonstrated both shorter mRNA molecules for α_1 (I) chains and a deletion in the α_1 (I) chain gene in the DNA (M.L. Chu, Rutgers University). The second case is another, less severe form of Ostrogenesis imperfecta, where, remarkably, no α_2 (I) collagen chains are found at all in the skin[22]. While this case is obviously also a prime suspect for a deletion, in fact both pro-α_1 (I) and pro-α_2 (I) mRNAs are present in normal amounts in fibroblasts (D. Prockop, Rutgers University). An intriguing study was mentioned (P. Byers; J. Phillips, John Hopkins University) of a large Osteogenesis imperfecta family in which the disease segregates completely with a restriction site polymorphism near a growth hormone gene on chromosome 17. The suggestion is one of linkage of the disease gene (possibly the α_1 (I) chain gene) with the polymorphism, and is the first instance of this kind of analysis for a connective tissue disease. The analysis of more cases of the genetic connective tissue disorders is underway with the probes that are available, and the results will be of great basic as well as clinical interest. □

Onco Gen

from Peter Newmark

A paper on page 607 of this issue implicates the cellular gene known as c-*mos* in malignancies of antibody-producing cells or their precursors and illustrates a novel way of activation of an oncogene.

The c-*mos* gene is so called because it is the cellular homologue (and presumably the precursor) of the oncogene carried by the Moloney murine sarcoma virus. Whereas the viral gene is oncogenic, c-*mos* is not unless activated. In 1980 Blair *et al.* (*Science* **212**, 941) demonstrated activation of c-*mos* by the attachment to it of the long terminal repeat sequences of the Moloney murine sarcoma virus, probably on account of increased expression of c-*mos* under the influence of the long terminal repeats.

Rechavi *et al.* now demonstrate a completely different mechanism of activation of c-*mos* by — strange though it may seem — the replacement of a sizeable chunk of the gene by extraneous DNA. The mechanism is all the more important because it is not the result of an artificial construct but has been discovered in a chemically induced mouse myeloma.

The evidence comes from a comparison of the sequences of the normal c-*mos* gene and an abnormal version in the myeloma. The abnormal version, which was able to transform NIH 3T3 fibroblasts — the standard assay for an oncogene — had lost over 500 nucleotides from one end, including the information for the first 88 amino acids of the c-*mos* protein.

Intriguingly, a 159-nucleotide block of DNA immediately adjacent to what is left of c-*mos* has the hallmarks of a transposable genetic element, suggesting that a transposition has displaced some c-*mos* nucleotides and activated what is left.

The mechanism of the presumed activation is as much, if not more, of a mystery than in the case of the point mutation that seems to have produced the human bladder carcinoma oncogene (*Nature* **300**, 143 & 149).

In a note added in proof, Rechavi *et al.* claim that they have also detected a rearranged c-*mos* gene in a Burkitt's lymphoma. It is not yet known if the rearrangement involves a transposition but it does seem to be the consequence of a translocation from chromosome 8 to 14, bringing the c-*mos* gene into the proximity of the variable-region heavy-chain immunoglobulin gene in a fashion similar to that already reported for the c-*myc* gene (see *Nature* **300**, 403). □

Peter Newmark is deputy editor of Nature.

REVIEW ARTICLE

The T lymphocyte antigen receptor—paradigm lost

Jens Chr. Jensenius* **& Alan F. Williams**†

* Institut for Medicinsk Mikrobiologi, Odense Universitet, J. B. Winsløw Vej 19, DK-5000 Odense C, Denmark

It has been dogma that the antigen receptors on T lymphocytes must have recognition sites that are essentially the same as those of antibodies and that the receptors would be found if structures related to immunoglobulin V-domains could be identified on T lymphocytes. In a critical assessment we conclude that there is no sound basis for these views.

ANTIBODIES are the only well-characterized molecules that are known to bind foreign antigens in the immune response. An enormous range of antibodies can be produced with their different specificities being due to different amino acids in the combining site.

Lymphocytes are the only cells known to be capable of specific recognition of foreign antigen. This recognition results in the stimulation of antibody secretion and the activation of cells responsible for cell-mediated immunity. B lymphocytes (bursal or bone marrow-derived) give rise to antibody-secreting cells while T lymphocytes (thymus-derived) are responsible for the cell-mediated functions which include cytotoxicity and the control of other immune responses. Helper T cells provide a stimulus which is usually essential for the differentiation of B cells and cytotoxic T cells. Suppressor T cells turn off immune responses.

The antigen receptor on B lymphocytes is antibody and it has long been argued that the antigen receptor of T lymphocytes should at least use the antibody gene pool to encode its combining site regions. This point of view derives from the argument that it is unlikely that the problem of recognizing antigen should have been solved twice in evolution. However, we conclude here that there is no good evidence for the expression of antibody genes in T cells and many data suggest the contrary. Furthermore the discovery of molecules related to immunoglobulin (Ig) does not necessarily lead to the identification of immune receptor molecules.

Receptors on B lymphocytes

Figure 1*a* shows a model for a receptor IgM at a cell surface[1,2] and defines the terms used to describe antibody structure. The

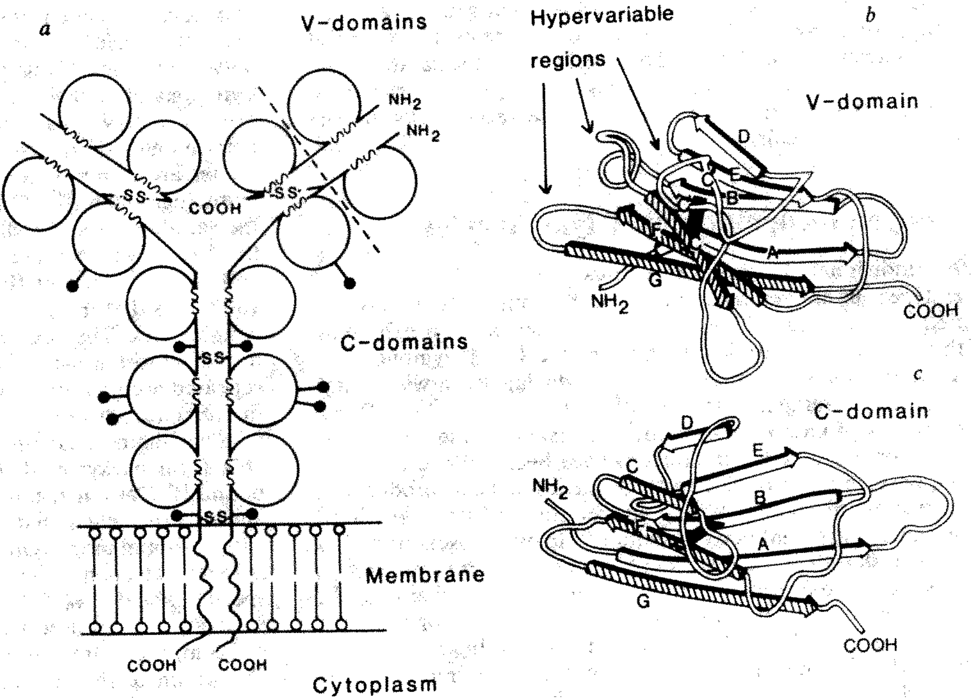

Fig. 1 The structure of receptor antibody. *a* Shows IgM antibody at a cell surface. The structure consists of two identical heavy (H) and two identical light (L) chains held together by disulphide bonds (SS symbols between the chains). There are two identical antigen combining sites, each formed from the N-terminal parts of one H and one L chain. The H and L chains can be divided into domains which show sequence homology (illustrated by circles) including a conserved intra-chain disulphide bond (≀ symbols). The N-terminal domains are called V domains (or regions) because their amino acid sequence varies to give different antibody combining specificities. The other domains are called C domains because their sequence is constant for any one L-chain type or H-chain class. The C domains for any one chain are collectively referred to as the C region. The symbols ⫯ show attachment points for N-linked carbohydrate structures. *b* And *c* show the folding pattern for the polypeptide of V and C domains respectively. In both sorts of domain anti-parallel β-strands form two β-sheets that are held together by hydrophobic interactions and the conserved disulphide bond. The bar indicates the conserved intra-chain disulphide bond and the letters, the β-strand sequences labelled sequentially along the sequence. The V domain has an extra loop of sequence in the middle and the β-strands in this are indicated by C′ and C″. The loops of sequence in V domains which are believed to form the combining site show great variation in amino acid sequence between different V domains and are indicated with the label: hypervariable regions (the domains are redrawn from ref. 3).

Table 1 Chromosomal assignments of genes for immunoglobulin and immunoglobulin related molecules in the mouse

Molecules		Chromosome (ref.)
Immunoglobulins		
Lambda:	$V_\lambda C_\lambda$	16 (152)
Kappa:	$V_\kappa C_\kappa$	6 (153)
H-chains:	$V_H C\mu\delta\gamma_3\gamma_1\gamma_{2b}\gamma_{2a}\varepsilon\alpha$	12 (154)
Major histocompatibility complex antigens		
Class I:	H chains	17 (19)
Qa:	H chain	17 (155)
Class II:	α and β chains	17 (19)
β_2-microglobulin		2 (156)
Differentiation antigen		
Thy-1		9 (19)
T receptors		?

antibody heavy (H) and light (L) chains can be subdivided into domains of about 110 amino acids which show sequence and structural homology[3,4] (Fig. 1*b*, *c*) but have quite different functions. The variable (V)-domains form the antigen recognition site while the constant (C)-domains of the H-chains function as determinants to be recognized by molecules of the immune effector systems (for example the complement cascade) which are triggered after antibody has bound antigen[5,6].

The genes for the V and C regions of any one immunoglobulin chain are linked but separated by a considerable distance on the chromosome. There are multiple *V*-domain genes but only one *C*-region gene for each chain. In ontogeny of B lymphocytes one V_L and one V_H gene is spliced to a new position closer to their respective *C*-region genes, committing the cell to one combining site[7,8]. In further differentiation genetic translocations can lead to expression of different C regions in the H chain[9] but the expressed V_H and L chains remain the same unless somatic mutation occurs.

The commitment of B cells to one combining site specificity can be demonstrated at the cellular level. Antibody at the B-cell surface can bind soluble or particulate antigen[10,11] and the antigen-binding cells for a typical antigen are usually found at a frequency of about 10^{-4}. These cells can be separated from other lymphocytes in various ways and have been shown to include the precursors for antibody-secreting cells of the appropriate specificity[12–14].

Antigen recognition by T lymphocytes

An individual T lymphocyte must have a limited set of endogenous antigen receptors since the immune functions carried out by T-cell clones are antigen specific[15]. In exhibiting this clonal specificity T lymphocytes are like B lymphocytes; another similarity is that T cells can distinguish a wide range of different antigenic structures[16–18]. However, T- and B-cell responses often do not coincide. For example a large number of minor transplantation antigens have been defined by T-cell responses but antibodies to them have not been produced[19]. Also some histocompatibility antigen mutants provoke T-cell responses but no antibody formation[20]. In other cases antibodies distinguish different antigens but T cells show cross-reaction[16]. This is commonly seen in immune responses to viral antigens[21].

One major difference between B cells and helper or cytotoxic T cells is that these T cells cannot directly bind soluble or particulate antigen that has not been processed by macrophages. Past claims to have identified antigen-binding T lymphocytes have been, at best, controversial. Acquired antibody can easily lead to false positives[22,23] as can the fact that the commonly used antigen TIGAL may bind to small numbers of T lymphocytes by cross-reaction with Fc receptors[24]. Acquired antibody is not a problem in studies with bursectomized chickens which have functional T lymphocytes but no B lymphocyte serum antibody. Antigen-binding T cells cannot be detected in these animals[22,24–26]. Similarly in mice there is no evidence for direct binding of antigen by helper or cytotoxic T cells if the criterion used is the enrichment or depletion of functionally active T cells on the basis of antigen binding[17,27–31].

The situation is different for suppressor T lymphocytes, which do show antigen binding[28,32,33] and also secrete factors which bind antigen[34]. In these properties suppressor T cells are similar to B lymphocytes and this analogy is supported by the finding that suppressor cells distinguish native and denatured antigen (as do B cells) whilst helper T cells do not make this distinction[28].

The difficulty in finding antigen-binding T cells became explicable when it was shown that T lymphocyte helper and cytotoxic responses require simultaneous recognition of foreign antigen along with self-histocompatibility antigen at the surface of an antigen-presenting cell[35,36]. Functional T lymphocytes will bind to a monolayer of macrophages which have been loaded with antigen[37]. Cytotoxic T lymphocytes usually recognize antigen along with class I histocompatibility antigens whilst recognition by helper T lymphocytes usually involves co-recognition of class II antigens[36].

The differences in antigen recognition by T and B cells suggest major differences in their receptors but do not rule out the possibility that T-cell receptors utilize at least a part of the antibody structure. Initially it seemed possible that T receptors were very similar to antibodies but that they possessed a different H chain. This is the IgX concept[38] (Fig. 2*a*) and is based on the fact that the different classes of antibodies are specialized for different effector functions. Subsequently the IgX model was modified to that shown in Fig. 2*b* in which the only immunoglobulin products shared with B cells are the V_H domains[39–41].

The search for T lymphocyte immunoglobulin

Antibodies have been widely used to search for immunoglobulin on T cells. Antibodies combine with a relatively small area of an antigen and antibodies against immunoglobulin are likely to recognize sequences at the exposed corners or surfaces of the immunoglobulin domains (Fig. 1*b*, *c*). By immunization between species it is simple to produce antibodies reacting with C regions of L chains and H chains and it is also possible to prepare anti-V-region antibodies which react with conserved determinants shared by many antibodies. In fact, anti-V antibodies are common components in sera raised against whole immunoglobulin[42,43]. Other anti-V antibodies can be against the variable parts of V domains (anti-idiotypes, see below) and these react with a minor sub-set of total immunoglobulin[44,45].

If the IgX concept (Fig. 2*a*) is right, anti-immunoglobulin antibodies that include anti-L-chain antibodies should label T lymphocytes. The failure to detect such labelling[25,46], by any but the most sensitive methods, must be one of the most repeated observations in immunology. In experiments using the fluorescence activated cell sorter the labelling of T lymphocytes with anti-immunoglobulin antibody is invariably indistinguishable from background (for example, ref. 47). If the T cells bound 10% as much antibody as B cells, this would be detected and it is thus clear that T lymphocytes do not routinely label with anti-immunoglobulin reagents at 30% of the B lymphocyte level as has been claimed[48]. However, using autoradiography specific labelling of T lymphocytes with anti-immunoglobulin antibody can be detected at about 100–1,000 molecules per cell compared with about 10^5 molecules for B lymphocytes[49,50]. The origin of the immunoglobulin detected has been studied in the rat using anti-L-chain allotype antibodies[51] and in the chicken using normal and bursectomized birds[52]. In both cases it was concluded that the small amount of immunoglobulin detected was acquired from exogenous sources. L chain was also searched for in extracts from T lymphocytes of the bursectomized chicken and <100 molecules per cell was detected[53].

To our knowledge there are no experiments in which the serological determinants of any immunoglobulin constant region have been found on T lymphocytes and been shown to be of endogenous origin (see controversial positives, below).

Given the above results and data from experiments with anti-idiotype antibodies[39,40] (see below), a model for the T-cell receptor as shown in Fig. 2*b* became accepted[41]. This is characterized by the expression of antibody V_H regions which should be detectable with anti-V-region antibodies specific for conserved determinants. Suitable antibodies can be prepared against the rabbit 'a' allotypes which are polymorphic determinants common to all immunoglobulin classes[54] and expressed on isolated H chain and V_H fragments[55]. Using these antibodies, attempts have been made to find molecules with V_H but not L-chain determinants by labelling of rabbit lymphocytes and analysis of cell extracts. In seven independent studies (refs 56–62) no evidence was found for these molecules, although expression at a few thousand molecules per cell may have gone undetected. Stimulation *in vivo* with antigen[62], or *in vitro* with mitogens or allogeneic cells[63] did not alter this negative result.

One report describes antigen-binding rabbit lymphocytes which express V_H but not L-chain determinants[64] and another, antigen binding molecules with these characteristics[65]. These results are difficult to evaluate without further analysis and an understanding of the nature of antigen binding T cells and factors (see above).

Other antibodies which react with V domains of a large fraction of immunoglobulin have also been produced. Two groups have used chicken or mammalian antibodies against rabbit V_H determinants distinct from the 'a' allotypes including antibodies that reacted only with free V_H or H chain[60,63]. V_H unassociated with classical immunoglobulin was not detected. Others have prepared antibodies against mouse V domains. A monoclonal anti-mouse V_H antibody did not react with T cells[66] and rabbit anti-mouse F_V (includes V_H and V_L) did not label thymocytes or T cells[67]. In contrast, similar rabbit antibodies against mouse V domains have been reported to inhibit antigen binding by T cells[68], but to show no binding to T-cell clones[17]. Again the positive effect is difficult to interpret due to the uncertainties about antigen-binding T cells. A rabbit anti-human V_H antibody was reported to show inconsistent labelling of human T cells[69].

To summarize, the evidence for V domains on T cells from experiments with widely reacting anti-V antibodies is unconvincing (particularly since there are a variety of ways that false positives can occur, see below).

Experiments with nucleic acid probes

Nucleic acid probes provide alternative reagents for searching for the expression of antibody genes in T cells. The probes can be used to search for mRNA in the T-cell cytoplasm or to examine the DNA of T cells to see if V-region genes have been moved in the manner that occurs in the commitment of B lymphocytes. In preparing probes DNA is copied (cDNA) from purified immunoglobulin mRNA and then cloned in plasmids to ensure the purity of the probe. Problems with the purity of T cells remain although B-cell contamination is excluded if T-cell clones or lines are studied.

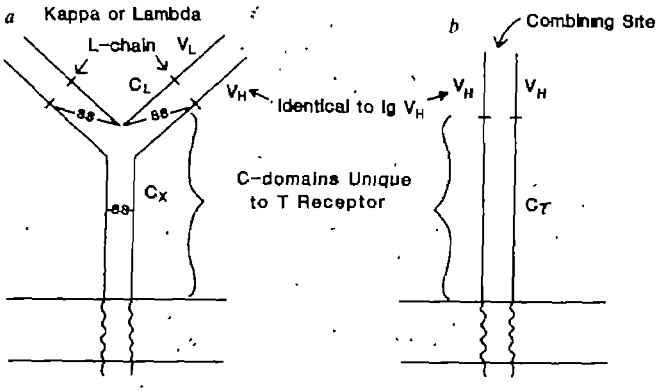

Fig. 2 Models for immunoglobulin related T lymphocyte antigen receptors. In both models the polypeptides differ from the homologous regions of B-cell antibody only in in C_χ or C_τ regions which are the products of postulated genes for constant regions expressed only in T lymphocytes (*a* based on ref. 38, *b* on refs 39–41).

Using cloned cDNA probes L-chain mRNA has not been detected in any T-cell lines[70,71]. Small amounts of κ mRNA were found in thymus[71–73] cell extracts but are likely to have come from plasma cells[72]. In a study using uncloned κ cDNA a reaction was detected in most thymus cells by *in situ* hybridization[74]. This result could be due to minor contaminants in the probe. RNA for the C region ($C\mu$) of IgM H chain has been detected in a proportion of T-cell lines[70,75] and thymocytes[72,73]. This $C\mu$ RNA is not likely to be B-cell-derived[72]. However, similar mRNA was also found in some myeloid cell lines[70] and in the T-cell lines no evidence for synthesis of $C\mu$ polypeptide was found in a rigorous study[76]. The mRNA detected did not appear to contain V_H sequences[77] and it seems to be an aberrant product made in a variety of early haematopoietic cells. V_H mRNA was not detected in cloned T cells or T hybridomas or functional T-cell lines in a study where four cloned V_H probes were used in conditions that allowed detection of a high proportion of all V_H mRNA in B cells[78].

Analysis of T-cell DNA showed no rearrangement of L-chain genes as occurs in B cells before immunoglobulin expression[71,79,80]. Also some studies found no rearrangement of H-chain genes[71,80,81]. In other cases, H-chain genes of some, but not all, clones or cell lines showed some rearrangement[75,79,82,83]. In B cells the construction of a functional H-chain gene involves splicing of a V_H segment, which codes for most of the V-region sequence, to a diversity (D) segment and a joining (J) segment[8]. In T-cell clones which showed V_H rearrangement splicing of the D and J segments occurred but rearrangement to produce a functional V_H gene was ruled out in detailed studies on two cytolytic T-cell lines[83].

At present, therefore, nucleic acid probes have not clearly aided the problem of identifying the T-cell receptor.

Controversial results not involving idiotypic determinants

The above data indicate that antibody gene products are absent from T cells. Yet, a number of reports claiming identification of T cell immunoglobulin or of cross-reacting molecules of relevance to the T receptor have to be considered.

Anti-immunoglobulin antibodies raised between species widely separated in phylogeny can give heavy labelling of thymocytes or T lymphocytes[84–87]. However, the reaction of rabbit antibodies against frog[88,89] or trout[90] immunoglobulin with thymocytes was shown to be due to a sub-fraction of antibody reacting with carbohydrate. A mouse monoclonal antibody against frog IgM did not label frog thymocytes[91]. The labelling of mouse thymocytes with chicken anti-mouse immunoglobulin antibodies was also due to anti-carbohydrate antibody[92]. This was of particular interest since the antibodies analysed were amongst those used by Szenberg *et al.* in their studies[87] claiming detection of mouse T-cell immunoglobulin.

Other claims for positive results have been made when immunoglobulin was detected by immunoprecipitation in extracts from T lymphocytes or thymocytes. Cone and Marchalonis have consistently reported positive results in studies[93–95] using cells that have been surface-labelled with ^{125}I. A number of other groups have not supported these findings[96–98]. Cone attributed success to the methods used to extract membrane proteins. Urea-acetic acid was initially favoured[93] and subsequently very low levels of detergent were recommended[94]. However, quantitative studies showed urea–

acetic acid gave very poor recovery of B-cell immunoglobulin[53,99,100] and very low levels of detergent might release membrane proteins as aggregates[101]. This could give misleading immunoprecipitations.

In biosynthetic labelling studies immunoglobulin has been detected in extracts from thymus cells[102,103]. However, the amount of thymus-derived immunoglobulin varies greatly between animals[53,100] and cannot be detected if thymus cells are treated to remove B cells before preparing extracts[98,104]. Relatively large numbers of plasma cells can be found in the thymus[105] and these are likely to be the source of thymus immunoglobulin. Removing all contaminating B cells is difficult since not all plasma cell precursors are readily removed by procedures commonly used to deplete Ig^+ cells from a lymphocyte mixture[106].

Finally, a general problem is the possibility of cross-reactions with the many immunoglobulin related membrane molecules (Table 1) which are not relevant to the T receptor. Anti-κ chain antibodies which react with β_2-microglobulin have been described[107,108].

Idiotypic determinants on T lymphocytes

Idiotypic antigenic determinants are displayed in the V regions of antibodies and may often be located in the loops of amino acid sequence making up the combining site[44,45]. In many—although not all[109,110]—cases they correlate with the combining site specificity of the idiotype-positive antibody. However, anti-idiotype antibodies do not necessarily react only with idiotype-positive antibodies. Anti-idiotype antibodies raised against antibodies specific for physiological effector molecules (for example, insulin) have been shown to recognize the physiological receptors for the molecule concerned[111–114] even though there is no evidence that these receptors are immunoglobulin related. Anti-idiotype antibodies labelled early haematopoietic cells which were immunoglobulin negative[115] and in another case an antibody to Thy-1 antigen reacted with the TEPC-15 idiotype[116]. Thy-1 is homologous to V domains[117] and its cross-reaction with TEPC-15 myeloma may be a chance event between two related molecules. Finally, a molecule was identified from a T-cell hybridoma which bound azobenzene-arsonate hapten and was recognized by antibodies to an idiotype associated with anti-hapten antibodies. However this was of no relevance to T receptors as the molecule has now been found in the cytoplasm of many cells[118].

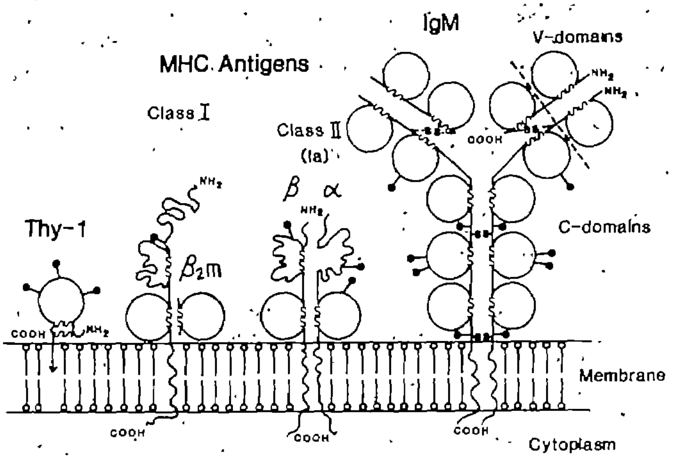

Fig. 3 Immunoglobulin-related molecules found at lymphoid cell surfaces. The diagrams are drawn roughly to scale and represent the polypeptide chains of: Thy-1 differentiation antigen; the major histocompatibility complex (MHC) class I and class II antigens; and IgM. The class I and class II antigens show homology with immunoglobulin C domains. Thy-1 shows homology with V domains. The circles represent immunoglobulin domains and their homologous regions in the other molecules with intra-chain disulphide bonds shown by ⁞ symbols. N-linked carbohydrate structures are shown by ⫯. In the MHC antigens the polymorphic determinants are found mainly in the heavy chains of class I antigens and the β chains of class II antigens. It is highly probable that the class I structure applies to Qa and Tl[145] differentiation antigens as well as to the class I histocompatibility antigens. Qa and Tl have β_2-microglobulin (β_2-m) in their structure and a gene which maps to the *Qa* region and may code for a Qa antigen has been sequenced[146] and shown to have an immunoglobulin-like segment as shown for the large chain of class I antigen. The diagrams are based on: Thy-1, refs 117, 131; MHC antigens, class I, ref. 147; class II, refs 36, 148–150; IgM, refs 1, 2. (Reprinted from ref. 151 with permission of the Biochemical Society.).

Given the above, it is clear that a reaction between an anti-idiotype antibody and a cell or cell product does not provide a definitive assay for the products of antibody V genes. Yet this interpretation has consistently been applied to studies which show that anti-idiotype antibodies can affect helper or suppressor T-cell functions *in vivo* or *in vitro* or react with suppressor factors in ill-defined cell extracts.

In a variety of systems anti-idiotype antibodies can be raised against a related set of antibodies which predominate in the response to a given antigen in a particular mouse strain[119]. The expression of the idiotypes in the antibody response is often linked to the immunoglobulin H-chain constant region allotypes. The anti-idiotype antibodies can stimulate helper or suppressor T lymphocytes specific for the given antigen[40,119–122]. These effects are only seen in the mouse strains which carry the immunoglobulin heavy chain haplotypes which correlate with the appearance of the idiotype in the antibody responses[40,121,122]. One interpretation of these data is that the T cells express the idiotype-positive V domains[40]. However, an alternative is that the idiotype determinants are expressed in non-immunoglobulin framework sequences and that T-cell clones expressing these determinants are selected by regulatory events dependent on the expression of the antibody idiotypes[123]. Until detailed molecular data on the T cell products are available the phenomena cannot be interpreted.

In other experiments suppressor factors in cell extracts have been shown to bind specifically to anti-idiotype antibody columns[34]. Again no molecular interpretation is possible until the factors are characterized in detail. It may not be too long before one has a detailed analysis of suppressor factor specific for keyhole limpet haemocyanin, because the translation from mRNA of products with this activity has recently been described[124]. This should lead to isolation of the suppressor factor genes.

Experiments on idiotypes of T-cell receptors for the major transplantation antigens appeared to hold hopes for molecular analysis. Binz and Wigzell prepared anti-idiotype antibodies against these receptors which labelled the functionally relevant cells and cross-reacted with antibodies of the same specificity[39]. They reported purification of the receptors and prepared rabbit and chicken antibodies against them[125,126]. This was all completed by 1976, yet there has been no further progress and no convincing repeats by other laboratories[127]. It is surprising that the pure receptor has not been used to raise monoclonal antibodies. It seems likely that the situation is not as clear as was at first thought and that difficulties of interpretation apply even though data which appeared decisive were reported.

In our view the idiotype data have been consistently over-interpreted and this criticism can also be made of recent data which claim the identification of allotypic determinants on the constant region of T receptors. Conventional[128] and monoclonal[129,130] alloantibodies have been prepared which react with determinants linked to immunoglobulin H-chain genes and it is claimed that they react with T receptors since the antibodies inhibit a reaction between T cells and antibody idiotypes[128] or react with T suppressor factors[130]. How reliable these systems are for assaying T receptors remains to be seen but it is disappointing that only cytotoxicity analysis, which is notorious for possible artefacts, has so far been used to determine with which cells the antibodies react[129]. Quantitative binding studies using the fluorescence-activated cell sorter have not been carried out

and it seems premature to claim that the determinants are part of the T receptor constant regions.

Immunoglobulin-related molecules at the cell surface

A surprising number of cell-surface molecules are now known to have segments homologous with immunoglobulin domains. These are illustrated in Fig. 3 and listed in Table 1. It is remarkable that the list includes all the molecules found on lymphoid cells with sufficient known sequence to allow analysis of homologies. It seems likely that more immunoglobulin related membrane molecules will be discovered.

Experiments looking for serological cross-reactions between antibodies and T-cell receptors imply an assumption that a relationship with immunoglobulin will be diagnostic for molecules concerned with immune recognition. The homologies with histocompatibility antigens may be considered consistent with this since histocompatability antigens are involved in the presentation of antigen to T lymphocytes. However, Thy-1 antigen cannot be thought of as having a unique role in immune phenomena since in different species its expression is conserved in neuronal cells and fibroblasts but not in lymphoid tissues[131]. Thy-1 is homologous with V domains[117] and this emphasizes the point that a relationship with immunoglobulin cannot in itself lead to the identification of an antigen receptor.

The genes for the immunoglobulin-related molecules map to six different chromosomes in the mouse (Table 1) and there is no reason why the T-cell antigen receptor genes should be linked to any of these. On the contrary the data suggest they might be quite independently located since there is no linkage between the immunoglobulin genes for H chains and κ and λ L chains.

Alternative possibilities

Given Fig. 1 it seems obvious to say that the T-cell receptor should be related to immunoglobulin as 'everything' else is. Yet this may not be so, and in Fig. 4 we present a proposal for the independent evolution of antibodies and T-cell receptors from the two arms of a primitive recognition system. We suggest that the role of the primordial immunoglobulin domain was to function as a ligand for triggering cell–cell interactions by binding to a recognizer, which was not immunoglobulin-like, on other cells. The Thy-1 glycoprotein may be a contemporary molecule with such a role[132,133]. In evolution, genes for both the primordial domain and its recognizer might have duplicated and diverged to produce a set of molecules for determining the specificity of cell interactions in tissue formation. This system may have given rise to antibodies and histocompatibility antigens at the time of vertebrate evolution. The role of the immunoglobulin Fc domains in triggering effector functions and of the histocompatibility antigens in controlling T-cell recognition would be directly analogous to the triggering role of the primitive set of immunoglobulin-related structures. The Fc-binding molecules of the immune effector systems may have evolved from the recognizer arm of the primitive system, and this may have also given rise to the T-cell receptors.

It could be argued that a distinction between ligand and recognizer in systems like this is semantic and also that both arms of the postulated system could be immunoglobulin-related. Amino acid sequences of the various Fc-binding proteins will show whether or not these constitute an independent family of molecules. Thus far the only relevant protein which has been sequenced in C1q and this shows no homology with immunoglobulin[134].

What next?

We conclude that there is now no good paradigm for thinking about T lymphocyte receptors in molecular terms. Different T-cell clones have different recognition specificities so T receptors must exist but their interaction with antigens is unlike that seen between antibodies and antigens. Somehow there is co-recognition of histocompatibility antigens along with foreign antigen on a presenting cell. The T-cell receptors are unlikely to incorporate any of the gene products seen in antibodies but they may be immunoglobulin-related. However, this does not help greatly in searching for T-cell receptors since many surface molecules are immunoglobulin related.

T-cell receptors can now be sought at either the protein or nucleic acid level. Suppressor T-cell factors are being purified[124,135–137] and their structure will be of interest since they are the only known T-cell products which seem able to interact directly with antigen. However, their combining sites may be quite different from those of helper and cytotoxic T cells which show co-recognition of self-histocompatibility antigen and foreign antigen. Another approach is to search amongst differentiation antigens recognized by monoclonal antibodies for molecules which are candidates for T receptors. A number of antibodies which inhibit or stimulate T lymphocyte responses have been described[138–143]. The molecules they recognize may be receptors for foreign antigen or self-histocompatibility antigen or other regulators of T-cell functions. A similar but possibly more direct approach is to look for monoclonal antibodies which distinguish between T-cell clones and thus perhaps recognize idiotypes of the receptors[144]. At the nucleic acid level characterization of genes which cross-react with immunoglobulin probes may yet be productive and T-cell-specific molecules can be sought at the level of mRNA. In all these approaches the evidence for relevance to T-cell receptors will be weak until sequence data are available. Only then will it be feasible to try and detect in T-cell clones with different recognition specificities molecules of varying sequences in a constant framework. If such molecules were T-cell specific and if antibodies to them inhibited T-cell functions at the level of primary recognition of antigen, we would be confident that the T lymphocyte antigen receptor had, at last, been identified.

We thank our colleagues for their criticisms and Mrs Christine Scott for assistance with the manuscript.

Note added in proof: Mouse monoclonal antibodies specific for common determinants of human V_H labelled a high proportion of B but not T lymphocytes[157]. A molecule which may be mistaken for T-cell immunoglobulin is gp70 of leukaemia viruses, which is immunoprecipitated from extracts of mouse lymphoma cells by chicken anti-mouse immunoglobulin antibody[158].

Hole 504B provides a reference section for correlation of in situ *petrological and geophysical studies with regional crustal models based on dredged samples and remote surveys; and, at least for the medium-spreading-rate Costa Rica Rift, Hole 504B confirms that the main features of the upper part of an idealized ophiolite sequence occurs in the oceanic crust.*

OUR knowledge of the nature of the ocean crust is drawn from three main sources: (1) studies of ophiolite complexes, (2) surveys using remote geophysical tools such as marine seismic reflection and refraction, magnetics, gravity, and heat flow, and (3) petrological and physical measurements on dredged and cored samples. Pioneers[1,2] recognized early-on that the various rocks dredged from the Mid-Atlantic Ridge were equivalent to the different components of an ophiolite sequence. Several models of the ocean crust have been proposed since which attempted to integrate the various data, but these were usually based on an ideal ophiolite lithostratigraphy (see, for example, refs 3–6). A typical ophiolite complex starts with a pelagic sediment cover resting on effusive pillow basalts, which grade downward into a basaltic dyke complex. This then grades into a plutonic sequence of gabbros and ultramafic cumulates. The lowermost member of the ophiolite sequence is made up of tectonized and metamorphosed ultramafics (ref. 7 and refs therein).

In seismic models of the oceanic crust[8–10], fresh or 'weathered' basaltic pillows and flows (Layer 2A) rest under pelagic sediments (Layer 1) and on metamorphosed pillows (Layer 2B), which in turn rest on metamorphosed intrusive dykes (Layer 2C). Originally called the 'volcanic layer'[2], Layer 2 is on average 2.5 km thick, but its thickness is extremely variable. On the other hand, the underlying 'oceanic layer' (Layer 3) is remarkably uniform in thickness, averaging ~4.5 km, and is thought to be made up of gabbros and more or less serpentinized ultramafics.

The total, seismically-determined thickness of the oceanic crust generally ranges from 5 to 7 km, whereas the total thicknesses of most ophiolite complexes do not exceed 4 km (ref. 7). This, coupled with chemical evidence, suggests that various ophiolites probably correspond to different types of tectonic environments. Thus, one is led to question the validity of using ophiolites as models of ocean crust. Another discrepancy between the ophiolite model and ocean crust is the rarity of dredged and drilled oceanic rocks which can be ascribed to a dyke complex. Finally, from published ophiolite studies one is led to believe that basaltic rocks from ophiolites generally display an increasing degree of pervasive alteration ranging from zeolite facies at the top of the pillow lava to greenschist facies at the bottom of this sequence, to amphibolite facies in the dyke complex. However, the rare detailed petrological studies of metamorphic rocks from ophiolite complexes[11] indicate polyphase and more localized metamorphism.

Leg 83 of the Deep Sea Drilling Project (DSDP) has established the most complete reference section to date through the upper oceanic crust, by deepening Hole 504B in the eastern equatorial Pacific to a total depth of 1,350 m below the sea floor (BSF), 1,075.5 m into basement (Fig. 1). Hole 504B had been drilled to 836-m BSF 2 yr previously during Legs 69 and 70, for the purposes of investigating young, geothermally-active ocean crust[12,13]. In November–December of 1983, Leg 83 re-entered the hole, cored 514 m deeper into basement, and completed an extensive suite of geophysical experiments.

Hole 504B is located in 3,460 m water, 201 km south of the Costa Rica Rift (CRR), the easternmost arm of the Galapagos Spreading Center (Fig. 1). Site 504 is located on magnetic anomaly 3′, with an estimated age of 6.2 Myr. Young crust on the southern flank of the CRR passes through the equatorial high productivity zone, with a sedimentation rate of 50 m Myr^{-1}. The 274.5 m of sediment at Hole 504B are dominantly siliceous nannofossil oozes, of late Pliocene age near basement contact. The youngest chert yet found in the oceans occurs at the base of the sediments[12]. This chert is thought to have been formed by the high temperature within the thick pile of sediments overlying young oceanic crust[14].

Geothermal setting and temperature measurements

In the vicinity of Site 504, the thick sediment has formed an effectively impermeable seal to convective heat loss from the cooling plate. This is demonstrated both by the pattern of surface heat flow measurements[15,16], and by downhole temperatures[12,17,18], all of which indicate surface heat flow in agreement with conductive plate cooling predictions of 190–

0028–0836/82/500589—06$01.00

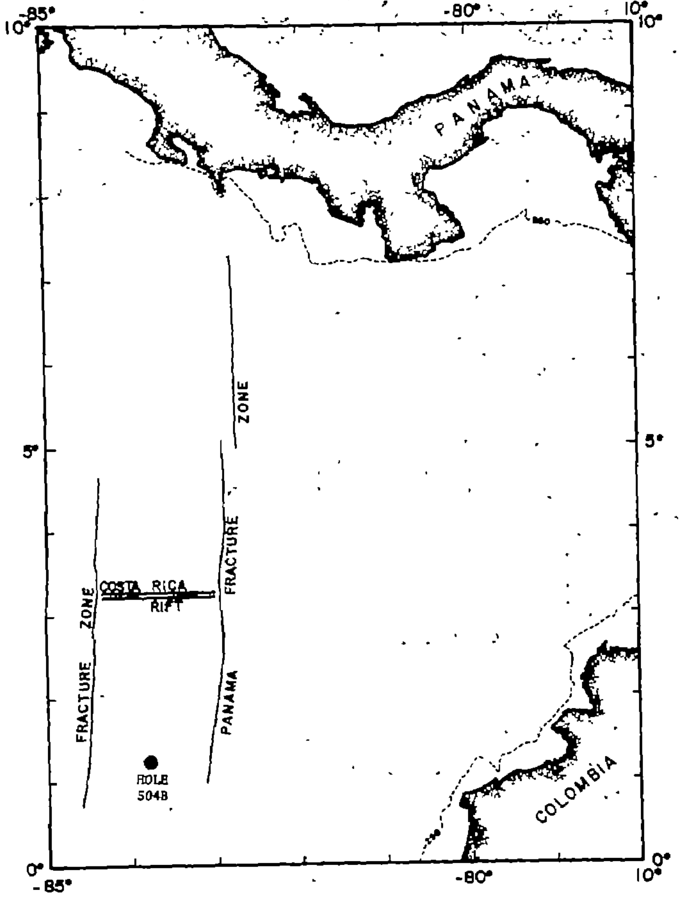

Fig. 1 Location of Hole 504B.

200 mW m^{-2}. Closer to the spreading axis, where the sediment cover is thinner and the basement topography is considerably rougher than at Site 504, surface heat flow values are much less than predicted, presumably due to hydrothermal convection[16].

Downhole temperatures measured on Legs 69, 70 and 83 indicate that an equilibrium, predominantly conductive geothermal gradient holds to the full Hole 504B depth (Fig. 2). However, after Leg 69 drilling punctured the sediment seal, borehole temperatures to a depth of ~360-m BSF were strongly depressed below values measured in the sediments. This was interpreted to indicate flow down the hole of ocean bottom water into the uppermost ~100 m of basement, at a December 1979 rate of 6,000 l h^{-1} (ref. 17), decreasing to ~1,500 l h^{-1} in November 1981[18]. This drawdown is convection forced by basement pore fluid underpressures, which have been attributed to hydrothermal circulation in the basement[19]. The basement underpressure originally measured on Leg 69[19] must have significantly rebounded towards the equilibrium hydrostatic pressure after 2 yr of mass flux down the hole into the formation: a mass of seawater of the order of 50×10^6 kg.

Lithostratigraphy

The combined drilling efforts of Legs 69, 70 and 83 have resulted in the penetration in Hole 504B of 1,075.5 m of oceanic basement, with a total recovery of 224 m, corresponding to an average of 20.8%. The lithostratigraphy is shown schematically in Fig. 3 and is summarized below. The upper 575 m of basement consists of intercalated pillow lavas, pillow breccias, hyaloclastites, minor flows, and localized flow and tectonic breccias.

The upper zone is underlain by a 209 m transition zone consisting of pillows, minor flows, and dykes. The upper boundary of the transition zone has been placed at a depth of 846-m BSF, where the first three dykes were encountered within 5 m of each other. Pillow sequences are more abundant, continuous and heavily brecciated at the top of the transition zone than at the bottom. Fracturing and brecciation are particularly extensive from 911 to 929-m BSF within a large pillow sequence where a mineralized stockwork occurs. Towards the base of the transition zone the pillow units become thinner, and massive units (with a uniform, medium coarse-grained texture, lacking chilled margins) and dykes progressively increase in frequency. The massive units cannot be identified explicitly as dykes because they lack chilled margins.

Dykes were identified by the intrusive nature of the contacts determined in hand specimens and thin sections. Macroscopically, the contacts range from brecciated to razor sharp. In contrast to chilled pillow rims, glass is never encountered in dyke margins and extensive quench morphologies are rare. Dyke margins are best described as having a dense cryptocrystalline to very fine-grained equigranular texture (crystals <0.004 mm in size). Microlites and microphenocrysts are

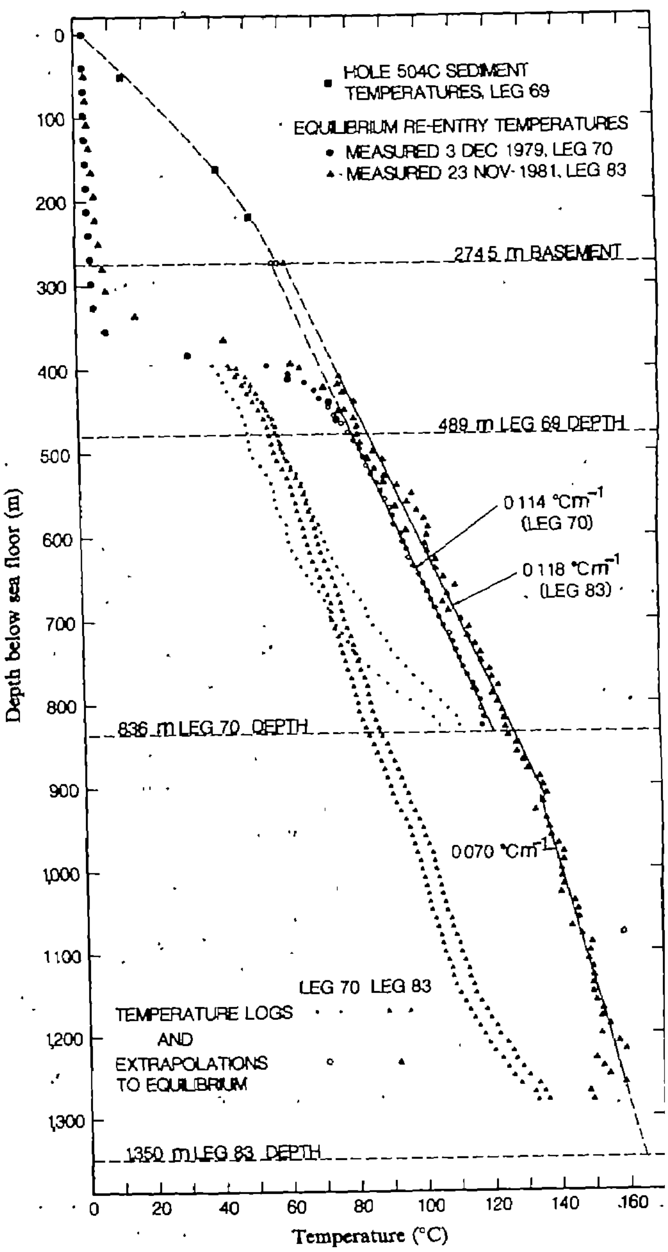

Fig. 2 Borehole temperatures measured on Legs 69, 70, and 83. Equilibrium re-entry temperatures (circles for Leg 70 and crosses for Leg 83) indicate drawdown of bottom water into the upper ~100 m of basement, at a decaying rate. Below this aquifer, extrapolation of temperature logs to equilibrium indicates a conductive heat flow of ~190 mW m^{-2} (from ref. 18.)

nearly always preferentially aligned parallel to the contacts and disaggregated material from the host basalt is also commonly observed at the margins of the intrusive material.

The last recovered pillow was identified at 1,055-m BSF; this depth was chosen by the shipboard petrographers as the boundary of an underlying zone composed predominantly of massive units and dykes in which no pillows were recognized. This unit is interpreted as a sheeted dyke complex, as predicted from ophiolite models of the oceanic crust. The dykes were recovered with one, and rarely two, chilled margins, most of which were steeply inclined (50–60°) to near vertical. Some of these chilled margins are highly brecciated, possibly as the result of forceful dyke intrusions. However, this zone as a whole is far less brecciated than those overlying it. The host material against which the dykes were chilled is always fine to very fine-grained. In contrast, basalts from the inner portions of dykes as a whole tend to have among the coarsest grain sizes recovered (medium coarse-grained, subophitic textures). Although the data are not yet sufficient for a convincing argument, this observation may indicate that dykes tend to intrude predominantly at the margins of previous dykes. This appears to be consistent with observations of one-way chilling documented in ophiolites[20]. Most of the basalts recovered from the lower zone are regarded as massive. Many of these exhibit significant grain-size variation; that is, fining towards one or both of their implied margins. Such massive units are probably dykes, although (per our definition of a massive unit) no chilled margins were recovered. However, the remainder of the basalts maintained a constant grain-size over the recovered interval and we can only speculate about their mode of emplacement.

The lavas in the uppermost part of Hole 504B are predominantly fine- to medium-grained, olivine + plagioclase ± clinopyroxene ± spinel phyric basalts; aphyric lavas become progressively more common with depth. These basalts can be divided into four petrographic categories on the basis of the phenocryst contents: (1) olivine–plagioclase–clinopyroxene phyric (~29% of the total recovery); (2) olivine–plagioclase phyric (13%); (3) variable olivine–plagioclase–clinopyroxene phyric with accessory chrome spinel (19%); (4) aphyric (40%).

Basement geochemistry

The least-altered basaltic rocks recovered from Hole 504B are remarkably uniform in their vajor oxide composition. Moreover, no chemical distinction can be made amongst the various petrographic or lithological types. Within the 1,075.5 m basement section, only three lithological units, 14, 18 and 2 m thick, differ significantly from all the other units. These basalts are characterized by higher TiO_2 and P_2O_5 concentrations (1.2–1.4% and 0.14–0.20%, respectively) and by an enrichment of LIL-elements, whereas most of the Legs 69 and 70 basalts are strongly LIL-element depleted[21].

A general characteristic of the rocks cored during Leg 83 is their high MgO (up to 9.78%) and their very low K_2O content, which is <0.02%. No systematic downhole variation was observed for the major oxides except MgO and K_2O (see section on alteration). However, there are some minor but irregular variations with depth, which are related to specific lithological units and indicate that limited shallow-depth fractionation processes were operative. The oxide means obtained on Leg 83 rocks are almost identical to those found in Legs 69/70 basalts and their confidence limits in all cases overlap. On a dry weight normalized basis, most rocks analysed vary within the following limits: SiO_2, 49.9% ± 0.9; TiO_2, 0.92 ± 0.1; Al_2O_3, 15.7 ± 0.8; FeO_t, 9.05 ± 0.5; MgO, 8.60 ± 0.6; CaO, 12.9 ± 0.3; K_2O, 0.20 ± 0.1 (Leg 69 section), 0.07 ± 0.04 (Leg 70 section) and 0.02 (Leg 83 section); P_2O_5, 0.08 ± 0.02.

Similar ranges of variation were also obtained on fresh basaltic glasses from the upper part of the hole drilled during Legs 69 and 70. These results suggest that the whole rock analyses (with the possible exception of MgO and K_2O) reflect the primary composition of the rocks and might represent magma compositions. Judging from the high mg values (where $mg \equiv Mg^{2+}/(Mg^{2+} + Fe^{2+})$), which range from 0.62 to 0.70 and average at 0.67, these magmas were rather primitive or unevolved, and had experienced only a small degree of crystal fractionation before their eruption or intrusion. This indicates either a short residence time within the magma chamber and/or the existence of a large magma chamber which was steadily replenished by the same mantle source.

Assuming that the least altered basalts of Leg 83 have similar trace element composition as those from Legs 69/70, it can be concluded that the magmas were derived from a LIL-element depleted mantle source. As a working hypothesis we assume that basalts of the three exceptional units were generated within very small 'pockets' of less depleted mantle material residing below the magma chamber.

Alteration

Alteration of basalts in Hole 504B can be divided into different depth zones based on the presence of various secondary mineral assemblages (Fig. 4). Secondary mineral occurrences from 275 to 585-m BSF are similar to those commonly observed in drilled submarine basalts altered at low temperatures ('submarine weathering'; refs 22–25). Alteration of the rocks in this interval is interpreted to be the result of superimposed stages of oxic alteration ('iddingsite' and celadonite–nontronite mixtures replacing olivine and filling voids in alteration haloes around cracks) and sub- to anoxic alteration (saponite replacing olivine and filling voids throughout the rocks).

The interval from 528 to 572-m BSF is characterized by the presence of Na–Ca zeolites in relatively frequent thick veins and replacing plagioclase in 1-cm wide alteration haloes around these veins. These zeolite veins and associated wallrock alteration in this zone are interpreted to be the result of a later localized stage of hydrothermal alteration superimposed on the previous alteration at lower temperature[26].

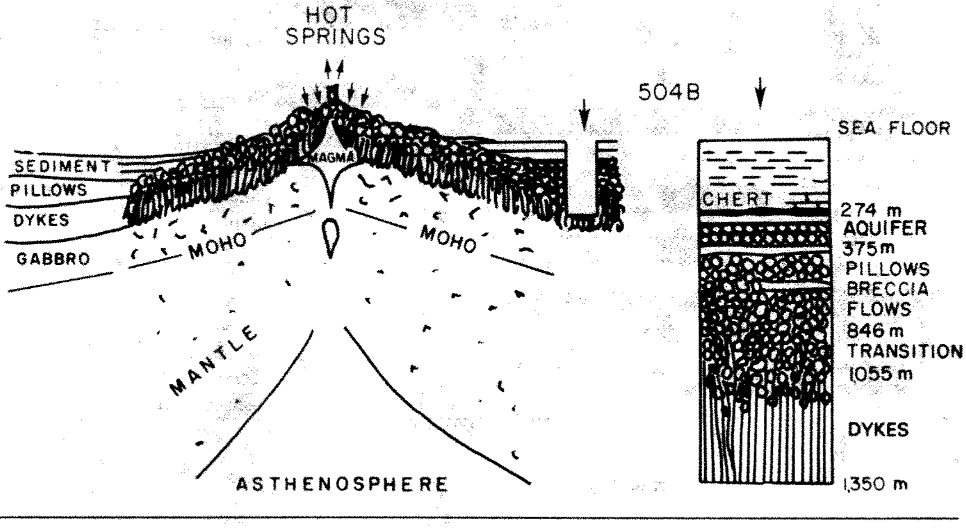

Fig. 3 Schematic cross-section of the Costa Rica Rift, with a highly generalized lithostratigraphy based on Hole 504B recovery and Leg 83 geophysical results.

From 585 to 889-m BSF, alteration is characterized mainly by the occurrence of saponite replacing olivine and filling voids. Secondary minerals in this interval shown in Fig. 4 also occur in veins, with quartz and pyrite abundances generally increasing with depth. Based on mineralogical data and bulk rock oxygen and stontium isotopic data, alteration reactions are interpreted to have occurred in sub- to anoxic conditions either with seawater at low water to rock ratios, or with seawater-derived fluids that had previously reacted with basalt[26,27]. This stage resulted in the bulk of the alteration observed, characterized mostly by the formation of smectite. Preliminary oxygen isotopic work on isolated smectite and anhydrite suggests that alteration occurred at 60–110 °C (refs 26, 28).

From 889 to 1,350-m BSF, olivine is generally totally replaced by, and interstitial areas filled with chlorite, although smectite or smectite–chlorite mixtures occasionally occur. Titanomagnetite is partly replaced by sphene, and plagioclase is partly replaced by albite, chlorite and minor laumontite. Actinolite occurs as alteration rims of clinopyroxene below 968-m BSF. The above minerals also occur in veins and cementing breccias, whereas the other secondary minerals in this interval (Fig. 4) only occur in veins or breccias.

Based on vein relationships, experimental data[29], and analogy with Icelandic geothermal fields[30,31], alteration from 889 to 1,350-m BSF is interpreted to have occurred in at least two stages at successively decreasing temperatures. The first stage resulted in the formation of actinolite, chlorite, sphene, albite, pyrite, and possibly epidote and quartz. Temperatures were at least 230 °C, and were >280 °C where actinolite formed (below 968-m BSF). During the second stage, laumonite, scolecite, pyrite, minor amounts of calcite, and possibly chlorite and prehnite formed at temperatures <235 °C. The occasional occurrences of smectite below 889-m BSF remain a problem, however, and may indicate either a lower temperature of alteration superimposed on a greenschist facies stage, or that smectite formed metastably at high temperatures.

A stockwork consisting of abundant veins of chlorite, laumontite, quartz, minor talc, sphalerite, chalcopyrite, and common large crystals (up to 1 cm) of pyrite in highly fractured pillow basalts occurs from 911 to 929-m BSF. Alteration in this stockwork occurred in two stages, similar to those listed above. The abundant sulphides in this zone can be explained either by mixing of a metal, S, and Si-rich hydrothermal fluid with seawater, as is suggested to occur at the Galapagos Spreading Center[32], or by a drop in temperature and/or pressure of this solution due to its rise and loss of heat to wall-rock.

Between 1,125 and 1,280-m BSF the rocks are generally less extensively altered and contain fewer and thinner veins than the overlying rocks. Olivine is completely altered to talc, magnetite, and smectite, whereas other igneous minerals are only very slightly altered. The smaller extent of alteration of these rocks may be due to the massive nature of the rocks and the scarcity of veins and cracks which would result in low permeability and restricted circulation of fluids.

From 1,182 to 1,350-m BSF anhydrite occurs in veins, and is interpreted to be a late alteration product. Anhydrite may have formed from heated Ca-enriched seawater in the current thermal regime, as predicted by experimental seawater–basalt reactions[33], or by mixing of hydrothermal fluids with seawater, as at 21 °N on the East Pacific Rise[34].

Below 1,280-m BSF basalts are more extensively altered than those in the overlying interval (1,205–1,280-m BSF), and the lowermost rocks recovered are among the most extensively altered.

There is a systematic but slight MgO increase and an associated K_2O decrease with depth as a result of hydrothermal alteration. H_2O+ is generally $<1.0\%$ in the least altered rocks from Legs 69 and 70 part of the hole, but shows a maximum (up to 3.4%) between 980 and 1,075-m BSF, coinciding with a zone of extensive mineral replacement; it then drops again towards the bottom of the hole. CO_2 decreases from top (0.1–0.4%) to bottom of the hole, where it is $<0.02\%$ in most samples. Note that only the least altered rock samples were analysed, so the chemical changes due to alteration are minimal.

Physical changes down the hole

Leg 83 also conducted the most extensive set of geophysical logs and experiments yet in the Deep Sea Drilling Project (Fig. 5), including packer flow tests, large-scale resistivity[35], borehole televiewer and multichannel sonic logging.

Geophysically, the upper oceanic crust sampled at Hole 504B consists of three distinct units. The upper ~100 m of basement is an aquifer of rubbly pillow basalts, breccia zones and a few massive flows. The entire section is fractured but not as extensively as deeper in the hole. Density, thermal conductivity, velocity (both P- and S-waves) and electrical resistivity are all low. Attenuation of seismic body waves along the wellbore and neutron porosity are high, and measured bulk permeability values are as high as those of a good producing oil sand (~60 millidarcies, md). An 'alteration analysis' carried out by cross-correlation of hydrogen-ion-sensitive neutron porosity versus porosity-sensitive γ-ray density logs corroborates Leg 69 core

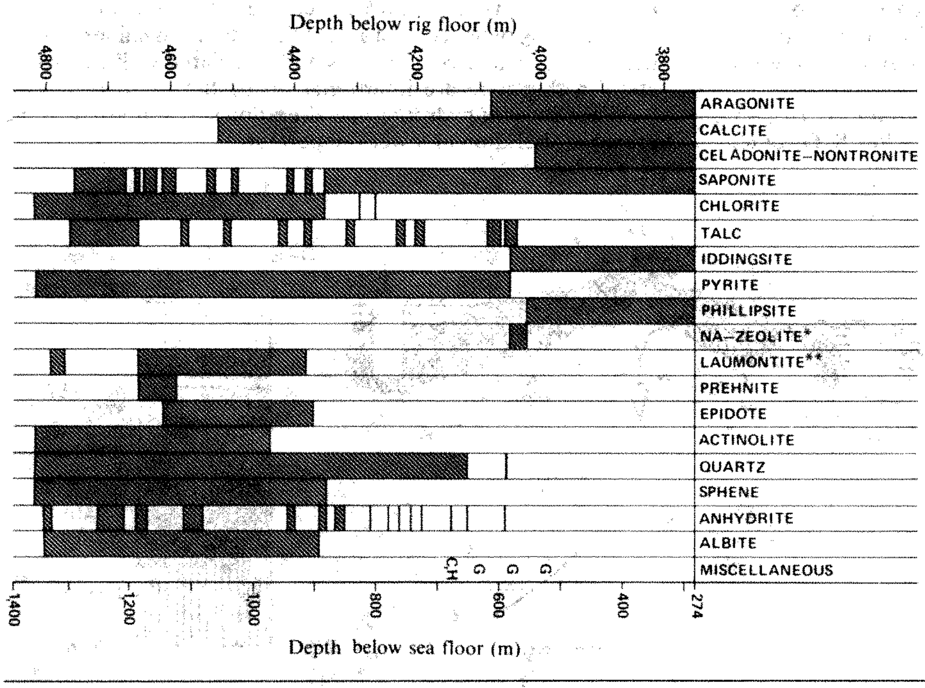

Fig. 4 Occurrences of alteration minerals in basalts recovered from Hole 504B. *, Natrolite, mesolite, thomsonite, analcite, apophyllite; **, including rate scolecite; G, gyrolite; C, chabazite; H, heulandite.

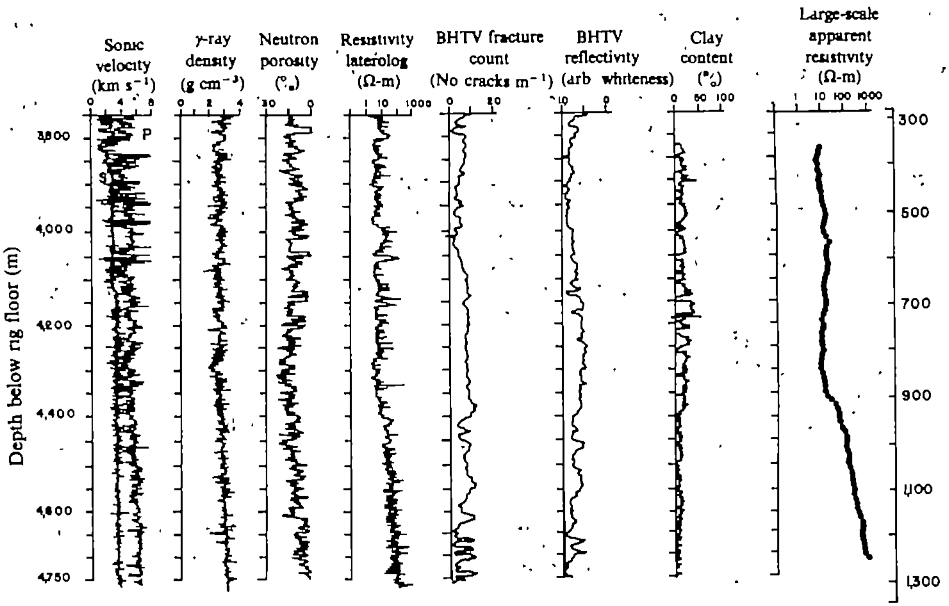

Fig. 5 Geophysical logs obtained from Hole 504B on Leg 83.

analyses[13] that show only moderate crack-filling by OH⁻ bearing alteration products such as clays and zeolites. Fractures thus appear to be largely open and filled with seawater[36]. Underpressures then turned this upper crust into an active aquifer system when the drill bit penetrated the chert and sedimentary hydraulic lid over this formation. We interpret this zone to be seismic Layer 2A.

From ~100 to 650 m into the basement (375–925-m BSF), increasing gradients in seismic P- and S-wave velocities, electrical resistivity and density, and a decreasing gradient in porosity are observed. Permeability at 475-m BSF has dropped to 4 md. The log cross-correlation alteration analysis shows a steadily increasing bulk content of hydrated minerals, peaking in a zone at 911–929-m BSF, the highly altered, sulphide-rich stockwork.

Borehole televiewer records show a steadily increasing content of fractures (almost all subhorizontal) and a decreasing wellbore reflectivity as the Layer 2A zone of large pillows appears to be replaced by much more extensive brecciation, smaller diameter pillows and fewer massive flows. Shipboard analysis of the cores recovered from this zone could not confirm the decrease in diameter of the pillows as observed in the BHTV records. We interpret this zone to be seismic Layer 2B. Relatively higher seismic velocity seems to be directly related to alteration products filling fractures and voids in this pillow unit[36]. Thermal conductivity, and magnetic susceptibility and intensity remain constant through this layer. Towards the bottom of Layer 2B, the first dykes are encountered.

Then, at about the depth of the stockwork, all of the physical properties change (Fig. 5). From 875 to 925-m BSF, electrical resistivity, density, and seismic velocity all show a slope change to a higher gradient. Porosity drops; sample thermal conductivities show a stepwise increase of ~25%. Magnetic intensity and susceptibility drop as most titanomagnetite is altered to sphene, but this drop is observed above the level where all other physical properties change. The borehole televiewer shows a drop in the intensity of fracturing and a rise in wellbore reflectivity. The log 'alteration analysis' shows a drop in the bulk content of hydrated minerals at this depth also. Permeability is 0.1 md over the lower 750 m of the hole, a drop of nearly three orders of magnitude. We interpret this to be the transition from seismic Layer 2B to 2C. Below, an increasing number of dykes leads into a sheeted dyke complex towards the bottom of the hole.

At 1,075-m BSF, magnetic intensity and susceptibility increase again as alteration pervasiveness subsides and more titanomagnetite remains intact.

The measured permeability decreases below Layer 2A much more abruptly than was previously expected, because alteration has plugged the plumbing in Layer 2B. The primary porosity of the rocks forming Layer 2C was already very low before alteration locally reduced it further. We cannot determine whether this permeability stratification has existed since the ridge axis or whether Layer 2A is 'disappearing' upwards as alteration products progressively replace seawater in fractures and pore spaces of the aging upper crust. If the former is the case, it suggests that much shallower, more horizontally-vigorous hydrothermal convection occurs on mid-ocean ridges than was previously thought.

Conclusions

Leg 83 of the DSDP has established the most complete reference section to date through the upper oceanic crust by deepening Hole 504B to a total depth of 1,350 m below the seafloor, or 1,075.5 m into basement. A maximum temperature of 135 °C was measured at the bottom of the hole, estimated to reach ~165 °C after the disturbance due to drilling has decayed. The 274.5-m thick chert-based sediment cover has sealed the crust to convective heat loss, so that if the crust at Site 504 is assumed to have aged through an earlier, hydrothermally-driven cooling phase, then crustal temperatures must have re-equilibrated upwards to present values as the sediment cover sealed off the basement.

The upper ~100 m of the basement consists of a relatively permeable (~60 md) aquifer made up of pillow lavas and breccias, and a few massive flows. Fractures appear to be open and filled with seawater. This is thought to be seismic Layer 2A. From 375 to 850-m BSF more pillow lavas, breccias, and minor massive flows of seismic Layer 2B were encountered, while the frequent fractures in this interval are filled mainly with smectite. The interval 846–1,055-m BSF corresponds to a transition zone with decreasing frequency of pillow lava recovery with depth and correlative increasing dyke recovery. A mineralized stockwork with Fe, Zn and Cu sulphides in laumontite, calcite, quartz, and chlorite veins was recovered in an extensively fractured and brecciated pillow lava sequence within this zone and may be the result of subsurface mixing of hydrothermal fluids with seawater.

The interval from 1,055-m BSF to the bottom of the hole corresponds to part of a sheeted dyke complex, seismic Layer 2C. Just below the mineralized stockwork, a major increase in density, thermal conductivity, velocity (both P- and S-waves) and electrical resistivity occurs. Conversely, the degree of fracturing, porosity and permeability decrease, the latter by nearly three orders of magnitude compared with the overlying formation. Magnetic susceptibility and intensity generally correlate with the extent of alteration of titanomagnetite.

The Layer 2B–2C transition based on physical properties is much sharper than the lithological transition from extrusive rocks to dyke complex (that is, ~50 m compared with ~209 m, respectively). Moreover the boundaries among the various types of alteration zones with depth do not coincide with any lithostratigraphic or physical property limits.

From the sediment–basement interface down to 585-m BSF (representing Layers 2A and 2B), basement alteration resulted from superimposed stages of sub- to anoxic and oxic processes, the latter at relatively high water–rock ratios. These stages resulted in the formation of celadonite–nontronite, 'iddingsite', pervasive saponite, and, finally, phillipsite and Ca-carbonates (aragonite, calcite). These processes and products are, on the whole, similar to 'sea floor weathering' observed in other DSDP holes. Veins of saponite and Na–Ca zeolites between 528 and 570-m BSF represent a localized later stage of superimposed hydrothermal alteration. Below 585-m BSF down to ~900-m BSF where greenschist-facies minerals appear, only sub- to anoxic alteration at low water–rock ratios has occurred.

Alteration of basalts below 889-m BSF is interpreted to be the result of at least two stages of alteration: (1) earlier formation of actinolite, chlorite, sphene, albite, pyrite, epidote and quartz at temperatures of at least 230 °C, and >280 °C where actinolite is present (below 969-m BSF); followed by (2) later formation of laumontite, scolecite, pyrite, minor amounts of calcite, and possibly chlorite and prehnite at temperatures <235 °C. Rocks in the interval 1,205–1,280-m BSF are much less extensively altered than over- and underlying rocks, however, due to locally lower permeabilities.

We thank Captain Dill and the crew and technical staff of the DV *Glomar Challenger* for their expertise, especially G. Norrie, A. C. Wheeler, and the drilling crew, who saved the hole on several occasions, leaving it open for possible future re-entry and deeper drilling.

In situ electrical resistivity was measured in DSDP Hole 504B to a depth of 1,013 m into oceanic basement. Apparent resistivities are about 10 Ω m *in about 600 m of pillow lavas, sharply increasing to nearly 1,000 Ω m in the underlying dykes. Bulk porosities calculated from resistivities show a distinct layering, apparently corresponding to geophysical layers 2A, 2B and 2C.*

THE circulation of seawater through fresh basalt has a vital role in the development of the chemical and physical nature of the oceanic crust. The modes and effects of circulation are themselves partially controlled by the variable permeability and porosity of the basaltic layer. As these crustal parameters probably depend on irregular fracturing of unknown scale, they cannot be reliably determined from dredged or cored samples. On the contrary, independent determinations of bulk porosity are essential in relating physical properties measured on recovered samples to the formation properties of the crust. Bulk permeability and porosity must be measured *in situ*, preferably from deep boreholes, at averaging scales large enough to escape the disturbance of drilling on the surrounding formation, as well as to include the effects of irregular fracture porosity.

0028–0836/82/500594—05$01 00

We report here the results of such an *in situ* experiment, a large-scale resistivity log in the deepest borehole drilled to date into the oceanic crust, Hole 504B of the Deep Sea Drilling Project (DSDP). Over the temperatures encountered in and around the hole (2–165 °C), the electrical conductivity of the pore fluid, essentially seawater, is 1–4 orders of magnitude greater than the intrinsic conductivity of the host basalt. Therefore, although not a direct measurement of porosity, our results were highly sensitive to the bulk porosity of the crust.

Measurement site

Hole 504B is ~200 km south of the Costa Rica Rift (Fig 1), in 6.2 Myr crust under 3,460 m of water. It was cored by three DSDP Legs, 69, 70 (refs 1, 2) and 83 (ref. 3), to a depth of 1,350 m beneath the sea floor, 1,075.5 m into basement (Fig. 2), nearly twice the basement penetration of any other oceanic borehole. Leg 83 clearly penetrated into the sheeted dykes and massive units of layer 2C (ref. 3). Due to the relatively poor core recovery (~20%), good geophysical logs were essential to the interpretation of the section and to relate studies of recovered samples to the bulk properties of the crust.

The 274.5 m of chert-based sediment have sealed the crust at Hole 504B from open circulation of seawater. Surface heat flow measurements[4] and downhole temperatures[5,6] indicate dominantly conductive heat transfer through the drilled section, at a value of 190±10 mW m^{-2}, consistent with predicted plate heat flow. No direct evidence was found for presently active hydrothermal circulation, although a vigorous, pressure-driven[7] drawdown of bottom water commenced when Leg 69 penetrated the sediment seal[5,6]. This drawdown is directed through the cased sediment into the upper ~100 m of basement, and it continues at a decaying rate[3,6]. It has had no discernible effect on the crust deeper than 400 m beneath the sea floor.

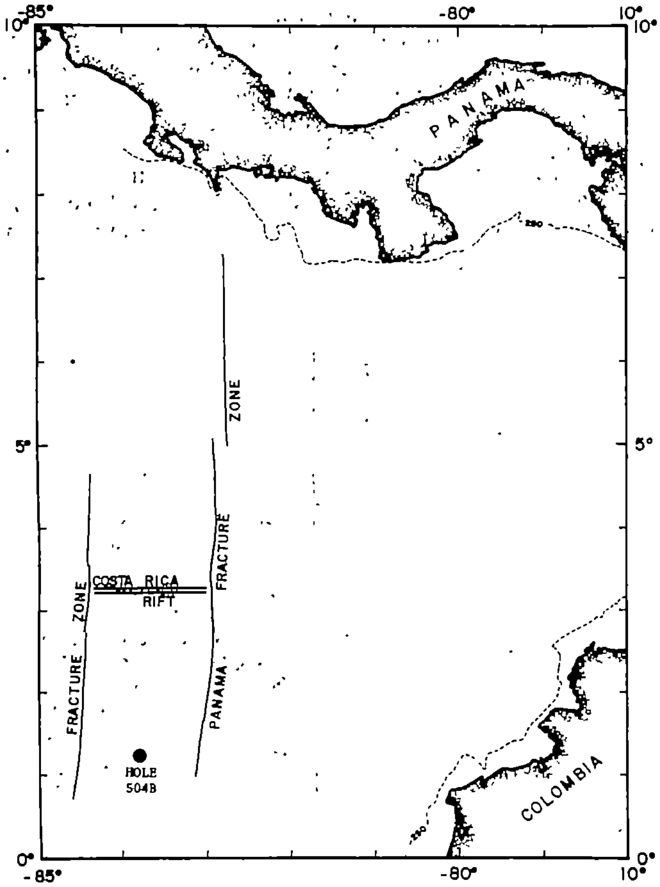

Fig. 1 Location of DSDP Hole 504B in the eastern equatorial Pacific.

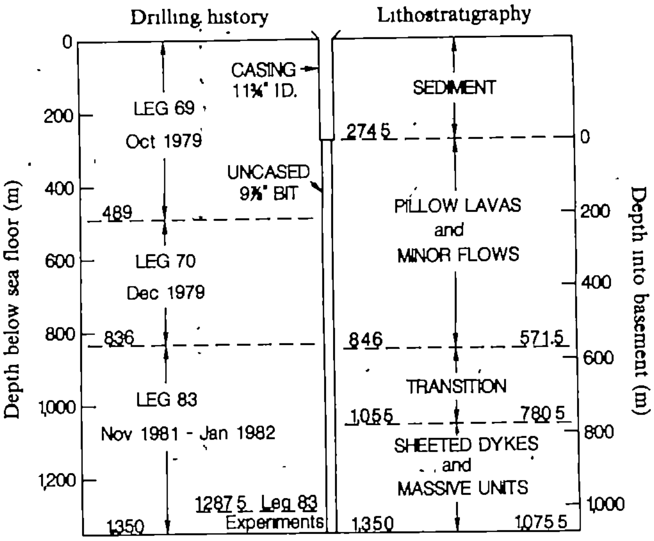

Fig. 2 Hole 504B drilling history (left) and generalized lithostratigraphy (right). The latter is based only on the ~20% core recovery[3].

Experimental procedure

The large-scale electrical resistivity experiment was first deployed on Leg 60 by Francis (see ref. 8 for details of the method). It was run twice in Hole 504B, first during Leg 70 to a depth of 836 m (ref. 9), and again during Leg 83 to 1,287.5 m. The experiment is a simple, long-spaced, d.c. resistivity log, for which the downhole configurations are shown in Fig. 3. A large current is passed from the ship down the armoured logging cable, through an insulated cable to a steel sinker-bar/current-electrode. It then passes through the formation and sea back to the ship. Despite the high conductivity of seawater, the long, narrow seawater return path up the borehole is relatively resistive (~5 kΩ km^{-1}), so that the current may be taken to return through the formation[8]. (Nor do the casing or armoured logging cable shunt the current return path[8].) Due to the resistivity of the formation, a potential gradient is set up in the hole, and it is sampled with several non-polarizing Ag/AgCl electrodes.

The experiment was run at discrete, stationary intervals: at each level, current was passed for about 10 s each under positive and reversed voltage. This allowed removal by averaging of any biases between electrodes due to possible ambient potential gradients in the hole. Currents and potential differences were measured to an estimated 3–5% accuracy on Leg 70, and to 1–3% accuracy with new equipment on Leg 83. On Leg 70, a 500-V power supply passed currents of ~6 A into the formation, and three potential electrodes were spaced 45, 91 and 183 m above the current source (Fig. 3). Potential differences between X and Y electrodes and Y and Z electrodes were recorded and the experiment was run at 25-m intervals. During Leg 83, a 300-V power supply was used, currents ranged over 3.5–4.3 A, and four potential electrodes were spaced 10, 20, 40 and 80 m above the current source. The hole was logged at 10-m intervals, with four potential differences recorded: 1–2, 2–3, 3–4 and 1–4. This redundancy showed excellent Leg 83 data quality: at every level, the sum of the smaller interval voltages duplicated the overall voltage to well within 1%. Although the hole was considerably deeper on Leg 83, a shorter electrode spacing was chosen, partly because the high temperatures in the hole were a threat (unrealized) to melt the insulated cable, and partly to bridge the range of resolution to the much shorter-spaced, focused, commercial resistivity logs also run.

The basic parameters measured were the potential differences between electrodes due to a known power source. Of the nine possible electrode pairs, potential differences were measured for six, and were obtained arithmetically for the other three. Measured voltages were in the 5–50 mV range in the pillow

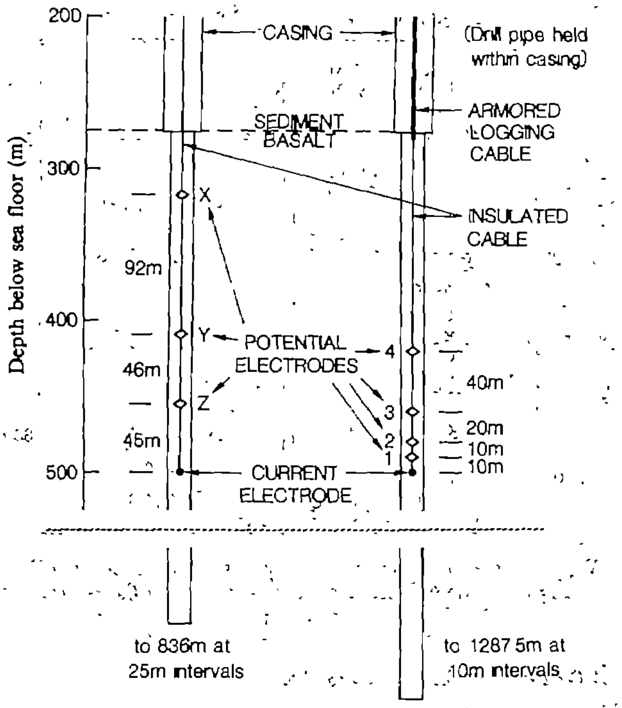

Fig. 3 Electrode configurations for large-scale resistivity experiments in Hole 504B.

lavas logged on Leg 70; when the dykes were logged on Leg 83, voltage differences of 10 mV–10 V were recorded. A 300-m section was repeat-logged on Leg 83; all measured voltages duplicated within 1%.

Apparent resistivity

For a real Earth, with a resistivity varying with depth (and possibly laterally as well), our measured voltage differences are related to the resistivity structure in a complicated, nonlinear fashion. The response of each electrode pair is a function of both the surrounding resistive Earth and of the spacings among potential and current electrodes[10]. In effect each electrode pair averages the Earth resistivity over a unique radial and vertical scale. We approximated true resistivities by converting voltage differences to apparent resistivities (ρ_a), calculated assuming a homogeneous Earth resistivity. With a zero potential assigned to the sea floor, and a current return at the ship, apparent resistivities were obtained by[8]:

$$\rho_a=\frac{2\pi\Delta V}{I}\left\{\frac{z_2}{h^2-z_2^2}-\frac{z_1}{h^2-z_1^2}\right\}^{-1}$$

with h being the depth beneath the seafloor of current source I, and z_1, and z_2 the depths of potential electrodes sensing the voltage difference $\Delta V(h>z_2>z_1)$. Since the potential gradient was more sensitive to resistivity variations where the current density was greater, that is closer to the current source, the depths assigned to apparent resistivities were those of the deeper potential electrode.

The electrode spacings were large enough relative to the hole diameter that no geometric borehole correction was necessary to the measurements. Moreover the large-scale experiment investigated far enough into the formation (~5–100 m) to escape the effects of the disturbed zone near the borehole, where temperature, pressure and porosity may have been unrepresentative of *in situ* conditions. We thus interpret our apparent resistivities as radially and vertically averaged *in situ* resistivities, with the poorly-determined averaging scales dependent on the true resistivity structure.

Figure 4 shows apparent resistivities calculated using five of the nine possible electrode pairs. These five pairs shared the same equidimensional ratios of spacings among the current and two potential electrodes (Fig. 3). Thus their averaging characteristics were similar, except that the longer arrays averaged farther into the formation. Indeed the five curves in Fig. 4 are increasingly smoothed, left to right, with increasing array length. The greater detail in apparent resistivities from the shorter-spaced Leg 83 electrode pairs probably reflects better resolution of small-scale vertical variations in resistivity; the smoother resistivities from the longer-spaced electrode pairs are probably more representative of the bulk properties of the crust.

The apparent resistivities in Fig. 4 are all consistent with bulk crustal resistivities on the order of 10 Ω m through the ~600 m of pillow lavas cored in Hole 504B. Below this level apparent resistivities increase sharply, approaching 1,000 Ω m in the sheeted dykes and massive units of layer 2C. As occurred with all other geophysical measurements in the hole, the transition in apparent resistivities is much sharper than the lithostratigraphical transition zone of ~209 m (Fig. 2) determined from

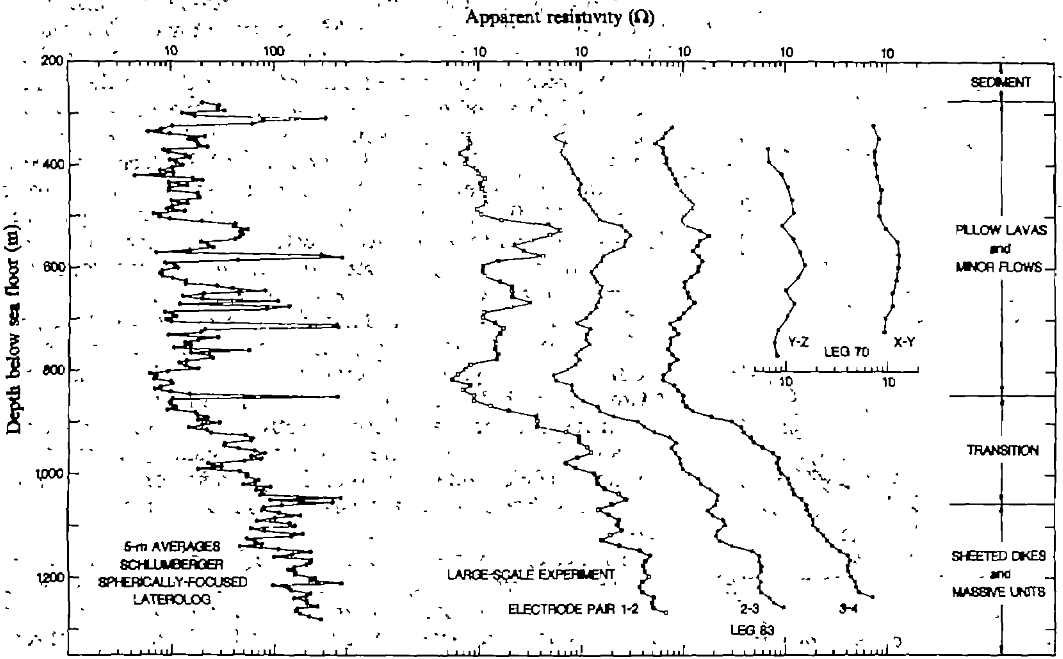

Fig. 4 (Left to right) 5-m averages of borehole-corrected resistivities measured by Schlumberger logging tool, five sets of apparent resistivities from the large scale experiment, and generalized lithostratigraphy of Hole 504B. Note logarithmic scales for resistivities, which are near 10 Ω m in the upper basement and approach 1,000 Ω m in the deepest dykes.

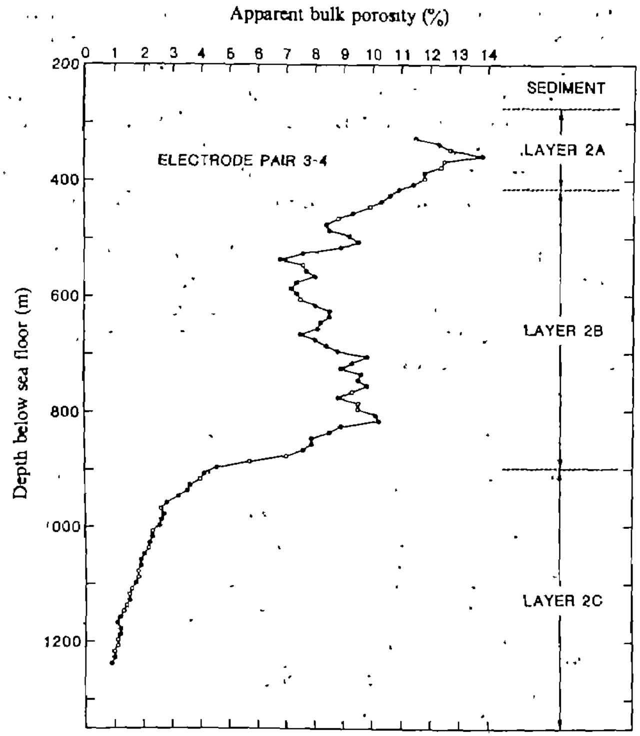

Fig. 5 Apparent bulk porosities calculated from apparent resistivities determined from electrode pair 3–4, using Archie's law with a temperature-corrected seawater resistivity: $\rho_a = \rho_{sw}\phi^{-2}$. On the right, divisions between layers 2A, 2B and 2C have been picked arbitrarily, based on changes in the apparent porosities shown here.

recovered cores[3]. Finer scale variations in apparent resistivities (and our later porosity estimates), particularly within the pillow lavas, may be related to the variable degree of alteration[3], either by partial filling of pore spaces, or because of the enhanced conductivities of alteration products. Comparison of our *in situ* resistivities with typical values of 5–3,000 Ω m measured on basalt samples[11–13] suggests a significant fracture porosity in the pillow lavas, sharply decreasing into the dykes below.

Considerably greater detail in apparent resistivities is shown by the much smaller-spaced Schlumberger spherically-focused laterolog (SFL) run on Leg 83, even when these borehole-corrected readings were averaged over 5 m (Fig. 4). As the radius of investigation of the SFL is relatively small (~0.5 m), some of this apparent detail is not directly representative of *in situ* conditions, but instead reflects some combination of exaggerated tool response at resistivity contrasts and the effect of the disturbed zone near the borehole. Nevertheless, average SFL resistivity values agree reasonably well with the large-scale values, except in the deeper, highly resistive section. We attribute this discrepancy to the greater contrast in the deeper section between the resistivity of the disturbed zone and *in situ* resistivity, as well as to possible errors in borehole-correcting the SFL response for the seawater in the hole. We take the large-scale resistivity values to be much better representative of *in situ* resistivity.

Bulk porosity from apparent resistivity

In commercial well logging, the porosity, ϕ, is often obtained from the measured resistivity, ρ_m, and the resistivity of the pore fluids, ρ_f, by application of the empirical Archie's law[14]:

$$\frac{\rho_m}{\rho_f} = a\phi^{-m}$$

with $a \sim 1$, $m \sim 2$. Although this relationship was developed for sedimentary rocks of relatively uniform porosity[15], it has been applied with reasonable success to samples of both oceanic[11–13] and continental[16,17] basement. We cannot rigorously justify application of Archie's law to *in situ* resistivity measurements in the oceanic crust, particularly because of the three-fold nature of the porosity[18]: electrical conduction may be due to vesicular (pore), crack or fracture porosity. The form of the resistivity–porosity relationship depends on the nature of the porosity: exponents near but possibly >2 have applied to measurements on basalt samples with dominantly grain-boundary (microcrack) porosity[11–13,16,17], whereas exponents <2 have applied in interpreting logging measurements in the fractured upper levels of oceanic basement[19,20].

As Hole 504B clearly penetrated through the highly fractured and partially sealed pillow lavas, into relatively unfractured and less altered dykes[3], we cannot realistically expect a single resistivity–porosity relationship to hold throughout. Nevertheless, we roughly approximated bulk porosities by applying Archie's law, compromising on an exponent of 2. The salinity of the pore fluids closely corresponded to that of seawater[21], so we used the temperature-sensitive resistivity of seawater. Based on laboratory measurements[22–24], we applied a linear relationship[9] of seawater conductivity, σ_{sw} (S m^{-1}), with temperature, T(°C),

$$\rho_{sw}^{-1} = \sigma_{sw} = 3 + T/10$$

over the ~160° range of equilibrium crustal temperatures[6].

Figure 5 shows apparent bulk porosities calculated using data from the longest-spaced Leg 83 electrode pair, 3–4, which yielded the largest-scale averages of *in situ* resistivity. Immediately obvious is a striking stratification of porosity, directly corresponding to layers 2A, 2B and 2C, as interpreted from other geophysical measurements in the hole[3]. We obtained bulk porosities of ~12–14% in the highly permeable aquifer, about 100 m thick, identified as a thin layer 2A (ref. 3), 7–10% in the deeper pillows that form layer 2B, and <3% in the dykes and massive units of layer 2C. These values are lower than porosity estimates of 13% or higher obtained from logging layer 2B in Atlantic DSDP holes in older crust[19,20].

A borehole seismic experiment[25] in Hole 504B showed a clear layer 2B/2C break, consistent with our sharp porosity change, but it showed no evidence for layer 2A. However, a ~100-m thick layer 2A may be beyond the resolution of both that experiment and conventional refraction techniques[26]. The Leg 83 sonic logs (Fig. 5 of ref. 3) are not inconsistent with our three-layer stratification of apparent bulk porosity.

Shipboard measurements of grain-boundary porosities of homogeneous basalt samples from Hole 504B yielded mean values of 5±2% in the pillows of layer 2A+2B (refs 12, 13), 3±2% for the entire Leg 83 section, and ~1% in the deeper dykes[27]. Thus our results corroborate interpretations based on other Leg 83 measurements[3,28], namely that: (1) a significant, unsealed fracture porosity exists in layer 2A; (2) fracture porosity is partially sealed by alteration products in layer 2B; and (3) very little fracture porosity exists in the dykes of layer 2C. This low layer 2C fracture porosity may have resulted from sealing by compression or infilling by alteration products. An alternative possibility must be considered—that the dykes may always have been relatively unfractured, which would probably require that hydrothermal circulation never penetrated significantly into layer 2C. In support of this hypothesis, we note that both fracture intensity and degree of alteration, determined *in situ* and from recovered samples, drop significantly in the dykes[3,28].

While we have no firm basis for confidence in our values of bulk porosity, we are confident that the porosity stratification revealed by applying Archie's law is not an artefact of the resistivity–porosity model used. In particular, the hundred-fold increase of resistivity into the dykes strongly implies a sharp reduction in bulk porosity, to 1% or lower. This result is consistent with the interpretation of a sea floor electromagnetic experiment on the flank of the East Pacific Rise at 21 °N, which suggests a similar increase of resistivity at a depth of ~1.4 km (ref. 29). In both that experiment and ours, the remarkable result was the surprisingly shallow level at which apparent resistivity sharply increases, and, by inference, fracture porosity and permeability to hydrothermal circulation decrease significantly.

Conclusions

We have successfully measured *in situ* electrical resistivity throughout nearly 1 km of layer 2 of the oceanic crust at Hole 504B. Crustal resistivities are about 10 Ω m in the pillow lavas forming layers 2A and 2B, and strongly increase to nearly 1,000 Ω m in the dykes and massive units of layer 2C. Bulk porosities estimated from crustal resistivities indicate three porosity layers directly corresponding to layers 2A, 2B and 2C. Our results suggest that there is almost no fracture porosity in layer 2C. The sharp increase with depth in apparent resistivity, and order of magnitude decrease in apparent bulk porosity, are highly consistent with the steep reduction with depth in bulk permeability also observed in the hole[3,7,30]. An important implication of the significant reduction in fracture porosity and permeability with depth, particularly into the dykes, is that any hydrothermal circulation must presently be limited to shallow crustal levels on the flank of the Costa Rica Rift (~1 km), or mostly confined to the pillow basalts. We speculate that hydrothermal circulation may have been limited in this way closer to the spreading axis.

We thank the officers and crews of the *Glomar Challenger*, in particular T. Gustafson, R. Current and P. Laughlin for invaluable assistance in conducting the experiments on Legs 70 and 83. We thank M. Salisbury and R. Stephen for constructive comments. This study was supported by NSF grants C-482, and OCE 81-17693.

Construction of influenza haemagglutinin genes that code for intracellular and secreted forms of the protein

Mary-Jane Gething
Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, UK
Joe Sambrook
Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724, USA

The DNA sequences encoding the amino-terminal signal peptide or the carboxy-terminal hydrophobic anchor have been deleted from a cloned gene coding for the haemagglutinin (HA) of influenza virus. The wild-type gene has previously been shown to be expressed with high efficiency from simian virus 40 (SV40)-HA recombinant vectors into a fully glycosylated protein that is displayed on the infected cell's surface in an antigenically and biologically active form. The anchor-minus HA also is glycosylated but is secreted efficiently into the medium. By contrast, the signal-minus HA is produced only at low levels, is not glycosylated and is located intracellularly.

HYDROPHOBIC amino acid sequences have a crucial role in determining the biosynthetic pathway and ultimate destinations of secretory and integral membrane proteins of eukaryotic cells. The precursors of such proteins invariably contain at or very near their N-termini a tract of hydrophobic amino acids which functions in the translocation of the nascent polypeptide across the lipid bilayer of the endoplasmic reticulum[1-6]. In addition, the majority of membrane proteins have at their C-termini another hydrophobic region that serves to anchor the completed protein into the lipid bilayer[6-10]. Analyses of both types of sequences from a large number of proteins have revealed a remarkable diversity of amino acid sequence, although hydrophobicity is always maintained. These results suggest that the essential difference between a secretory and an integral membrane protein is the presence or absence of an anchoring C-terminal hydrophobic peptide; and they raise the possibility that removal of the signal sequence might divert a secreted protein from its normal biosynthetic pathway into the cytoplasm of the cell.

Influenza virus haemagglutinin (HA) is the best characterized of all integral membrane proteins. Its complete amino acid sequence has been deduced[6,11-16] and its three-dimensional structure[17], organization into trimeric structures[17,18] and orientation with respect to the membrane[19] have been determined. In addition, the location of its major antigenic sites[20] and the points at which the protein is glycosylated[6,17] have been defined. Apart from the specialized features associated with its antigenicity and biological roles of attachment[21] and penetration[22,23], the structure of HA is characteristic of the major class of cellular integral membrane glycoproteins, containing typical terminal hydrophobic regions.

Recently the complete RNA gene for HA from the A/Japan/305/57 strain of influenza virus was converted to double-stranded DNA, cloned, sequenced and inserted into a

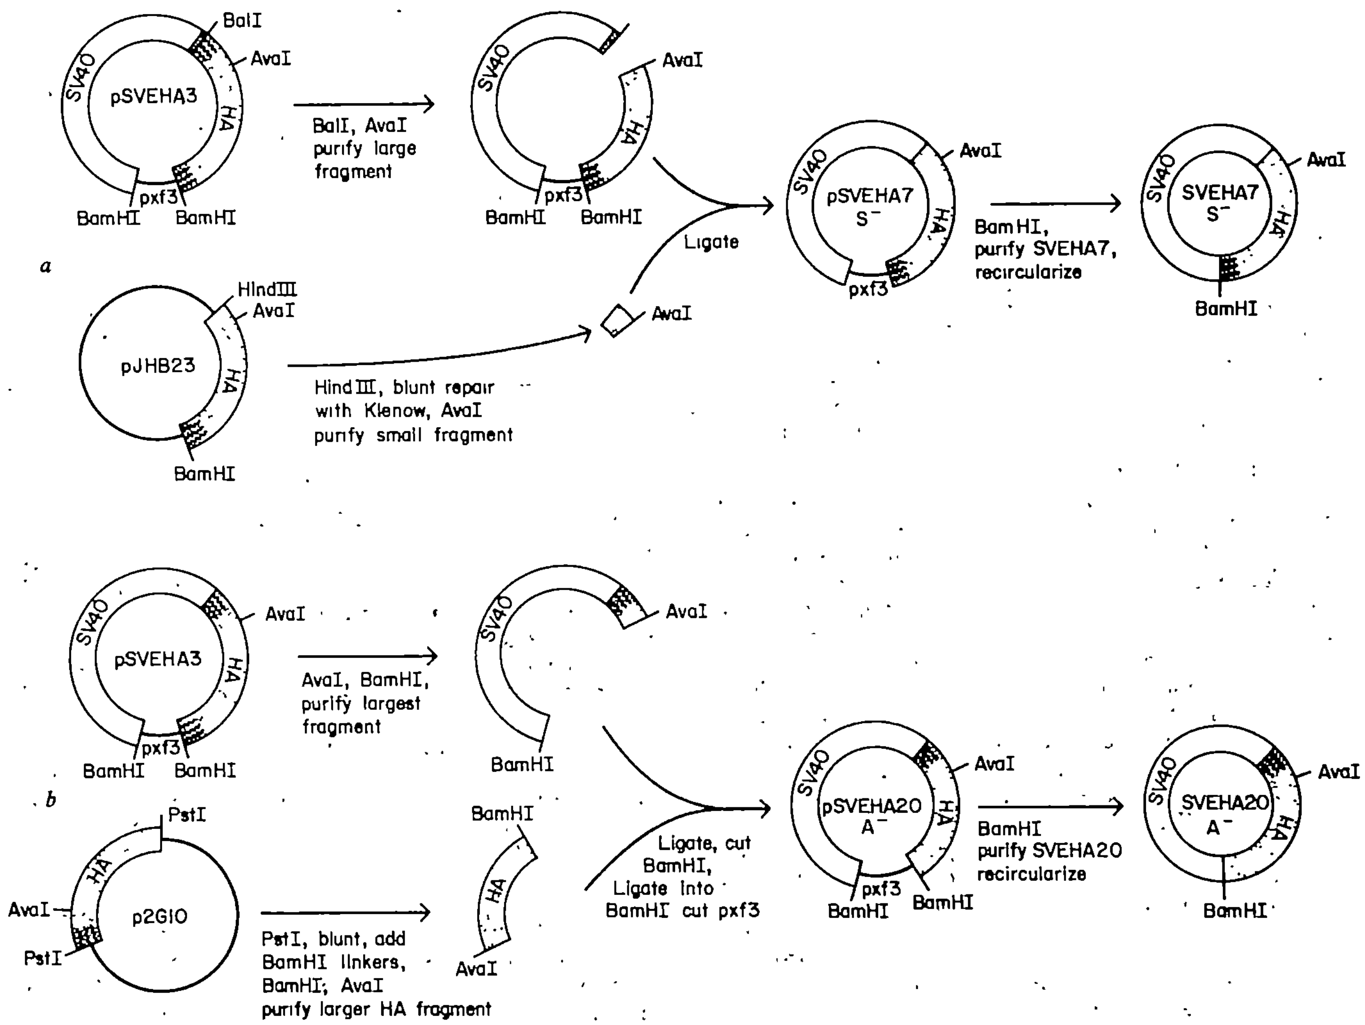

Fig. 1 Construction of recombinant vectors containing mutant genes that lack nucleotide sequences coding for the terminal hydrophobic regions of HA. *a*, The construction of SVEHA7-S⁻ (signal-minus) used two previously synthesized plasmids: pSVEHA3 which consists of the late replacement vector SVEHA3[25] (wild-type HA sequence) cloned into plasmid pXf3 (ref. 28), and pJHB23 which contains a truncated HA gene that was created by *Bal*31 digestion of the wild-type gene[25] and lacks the nucleotides coding for the signal peptide. pSVEHA3 was digested with *Bal*I and *Ava*I and the larger fragment was purified by polyacrylamide gel electrophoresis. (Restriction endonuclease digestions were carried out using the conditions recommended by New England Biolabs. Other cloning procedures were done as described in Maniatis *et al.*[28].) pJHB23 was digested with *Hin*dIII and the protruding tails were filled in using the Klenow fragment of DNA polymerase I. The plasmid was then further digested with *Ava*I and the smallest restriction fragment was purified by polyacrylamide gel electrophoresis. The two fragments were ligated using T4 DNA ligase and transfected into *E. coli* DH-1. A plasmid, pSVEHA7-S⁻, that had the desired structure was identified by restriction endonuclease digestion and the extent of the deletion was verified by determination of the nucleotide sequence across the junction[49]. This plasmid was then digested with *Bam*HI and the SV40-HA fragment was purified by gel electrophoresis and circularized by ligation at low DNA concentration (3 μg ml^{-1}) to produce the recombinant vector SVEHA7-S⁻. *b*, The construction of SVEHA20-A⁻ (anchor-minus) also used pSVEHA3, together with the plasmid p2G10 that lacks the HA nucleotide sequences coding for the C-terminal anchor peptide[6]. pSVEHA3 was digested with *Ava*I and *Bam*HI and the larger fragment was purified. p2G10 was digested with *Pst*I, the protruding tails were removed using S_1 nuclease and *Bam*HI linkers (Collaborative Research) were added. After digestion with *Bam*HI and *Ava*I, the 1,300-nucleotide HA fragment was purified. The two fragments were ligated and transfected into *E. coli* DH-1. A plasmid, SVEHA20-A⁻, that had the desired structure was identified and verified as described above, and the recombinant vector, SVEHA20-A⁻, was produced by purification and ligation.

variety of prokaryotic and eukaryotic expression vectors[6,24–27]. When this version of the HA gene is introduced into eukaryotic cells using vectors derived from SV40, it is expressed as a protein whose structure and biological properties are indistinguishable from those of authentic HA[25]. These cloned, expressing copies of the HA gene provide the material to analyse the effects of mutations on the structure and function of the molecule. Our initial experiments have focused on an analysis of deletion mutants of HA that lack the sequences coding for the N- or C-terminal hydrophobic peptides.

Construction of deletion mutants

The late replacement vector SVEHA3 consists of the coding sequences of the wild-type HA gene inserted into the late region of SV40[25]. This vector was used as the basis for the construction of two new vectors containing mutant HA genes that lack sequences coding for either the N-terminal or C-terminal hydrophobic peptides of the protein. In neither case did the deletions affect the placement of the HA coding sequences with respect to the upstream, controlling SV40 sequences. The construction of these mutants is described in Fig. 1. The signal-minus mutant (SVEHA7-S⁻) was derived from a plasmid (pJHB23) that contains a HA gene from which the 5′ non-translated sequences, the initiation codon and the nucleotides coding for the signal peptide had been removed by digestion with exonuclease *Bal*31 (ref. 25). A restriction fragment containing these truncated 5′ sequences was used to replace the sequences of the wild-type late replacement vector (pSVEHA3) lying between the *Bal*I site immediately following the ATG of the HA gene and the *Ava*I site at nucleotide 340 (ref. 6). This resulted in a mutant HA gene in which the initiation codon was fused in phase to the codon for the first amino acid of the

Table 1 Comparison of the properties of wild-type and mutant HAs produced from SV40-HA vectors

		SVEHA3 Wild-type	SVEHA20-A$^-$ Anchor-minus	SVEHA7-S$^-$ Signal-minus
Location		Cell surface	Secreted to medium	Intracellular
M_r (subunit)		75,000	72,000	63,000
Structure		Trimer	Trimer	?
Glycosylation		+	+	–
Red cell binding to infected cells		+	–	–
HA activity in cell extracts or medium		+	–	–
Cell–cell fusion (low *p*H dependent)		+	–	–
Molecules per cell (60 h post-infection)		6×10^8	1×10^9	1×10^6
Amount produced per 10 cm dish	(Extract)	200 μg	28 μg	0.5 μg
(60 h post-infection)	(Medium)	0	300 μg	0

The subunit structure of the purified proteins was determined by cross-linking with dimethyl suberimidate[18]. Red cell binding was assayed as described previously[25]. Cell–cell fusion was measured by the method previously described[23].

mature HA1 polypeptide (Fig. 2). The remainder of the HA coding sequences were unaltered. The anchor-minus mutant (SVEHA20-A$^-$) was derived from a plasmid (p2G10) containing a copy of the HA gene that lacks sequences coding for the C-terminal hydrophobic peptide and the putative cytoplasmic tail of the protein[6]. An *AvaI–BamHI* restriction fragment from this truncated gene was used to replace the corresponding wild-type HA sequence in pSVEHA3 (Fig. 1).

The mutant forms of the late replacement vectors were cloned in plasmid pXf3 (ref. 28) and propagated in *Escherichia coli.* The novel nucleotide sequences formed as a consequence of the deletions were determined and the amino acids encoded by the altered regions are shown in Fig. 2. The HA protein encoded by SVEHA7-S$^-$ lacks 14 amino acids that comprise the wild-type signal peptide. These sequences are replaced by a tract of three amino acids—Met, Glu, Leu—that is clearly neither long enough nor sufficiently hydrophobic to function as a signal peptide. On the other hand, the protein that is encoded by SVEHA20-A$^-$ lacks 38 amino acids from the C-terminus of the wild-type HA, including the hydrophobic anchoring sequence and the short hydrophilic tail. These residues are replaced in the mutant by 11 predominantly charged amino acids encoded by nucleotides from the GC homopolymer tails, the *BamHI* linker and a short stretch of SV40 sequence which precedes the first in-frame termination codon.

When the sequences of the mutants had been verified, the SVEHA recombinant genomes were excised from their plasmids by digestion with *BamHI*, purified by gel electrophoresis and recircularized by ligation at low DNA concentration[25]. The resulting circular DNA molecules were then introduced together with a helper virus genome, dl1055 (ref. 29), into CV-1 cells using DEAE–dextran as the facilitator[30]. Virus stocks were prepared as described previously[25].

Fig. 2 Comparison of the amino acid sequences coded by wild-type and mutant HA genes. The novel nucleotide sequences in the mutant HA genes, formed as a consequence of the deletions, were determined by the Maxam–Gilbert technique[49]. The amino acid sequences in the altered regions are compared with the wild-type sequence. Residues that are conserved between mutant and wild-type proteins are shown in capital letters, while those that differ are indicated by lower case letters. *** Indicates the probable beginning and end of the C-terminal hydrophobic sequence that is inserted in the lipid bilayer.

Expression of variant forms of HA from SV40-HA recombinants

Monolayers of CV-1 cells were infected at high multiplicity with vectors carrying the wild-type and mutant forms of the HA gene. Sixty hours later the media above the monolayers were collected and cell extracts were prepared[25]. The amount of HA antigen in aliquots of the supernatants and cell extracts was measured by a solid phase radioimmunoassay[25] and the results are shown in Table 1. HA expressed from the SVEHA3 vector is found exclusively in a cell-associated form: previous work[25] has shown that it is anchored into the plasma membrane. By contrast, the anchor-minus HA expressed from SVEHA20-A$^-$ is found in the medium in very high amounts, indicating that it is secreted from infected cells. The small fraction of HA antigen found in the cell extract may represent nascent protein that is still being transported within the cell or secreted material that has adsorbed to the cell surface. Both the wild-type and the anchor-minus HA are very efficiently expressed from the recombinant vectors, with up to 10^9 molecules of HA synthesized in each infected cell. Once the infection is well established (~20 h post-infection) serum-containing medium is no longer necessary for the continued production and secretion of HA. Thus, at 60 h after infection, 40 h after changing to serum-free medium, some 300 μg of essentially pure HA can be collected from a single 10-cm plate of cells infected with the anchor-minus mutant. Much less HA antigen is synthesized in cells infected with SVEHA7-S$^-$. Only 0.5 μg of HA is produced per dish, all of which is cell-associated.

Characterization of HA mutants

Supernatants and extracts obtained from cells radiolabelled with ^{35}S-methionine between 48 and 49 h after infection were immunoprecipitated and analysed by SDS-polyacrylamide gel electrophoresis (PAGE). Figure 3 shows the effects of the mutations on the size and location of the HA protein. As described previously[25], cells infected with SVEHA3 express a protein of molecular weight (M_r) 75,000 that is specifically precipitated by anti-HA serum from cell extracts but not from the supernatant medium. However, the HA protein synthesized during the 1-h labelling period by cells infected with SVEHA20-A$^-$ can be precipitated from both the cell extract and the medium, thus confirming that it is secreted from the cells. Both the wild-type and secreted forms of HA can be seen as major bands when the proteins in the labelled extracts are separated by SDS-PAGE without previous immunoprecipitation (Fig. 3). The slightly lower molecular weight of the secreted form of HA is as expected because the mutant gene encodes a protein that is 27 amino acids shorter than the wild-type molecule (Fig. 2).

A smaller protein, produced in much reduced quantities, is precipitated from extracts of cells infected with SVEHA7-S$^-$. In size, this protein is the same (M_r 61,000) as the non-glycosylated HA synthesized *in vitro* by translation of wild-type HA

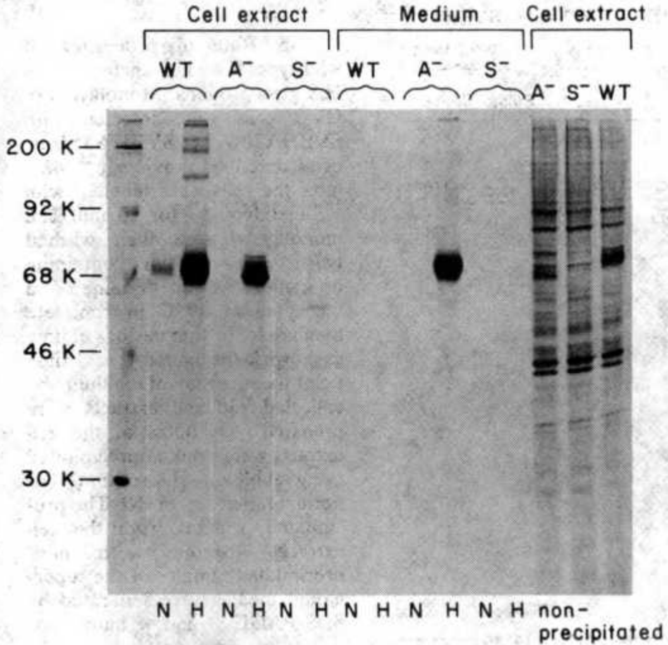

Fig. 3 Comparison of the expression of wild-type and mutant HA genes. Monolayers of CV-1 cells were infected with SVEHA3 (WT), SVEHA7-S⁻ (S⁻) or SVEHA20-A⁻ (A⁻) viruses as described previously[25]. 48 h later the cells were labelled for 1 h with ^{35}S-methionine and then the media above the cells were collected and cell extracts were prepared[25]. Aliquots of these samples were immunoprecipitated using rabbit anti-HA serum (H) or normal rabbit serum (N). The precipitated proteins were separated by SDS-PAGE and autoradiographed[25].

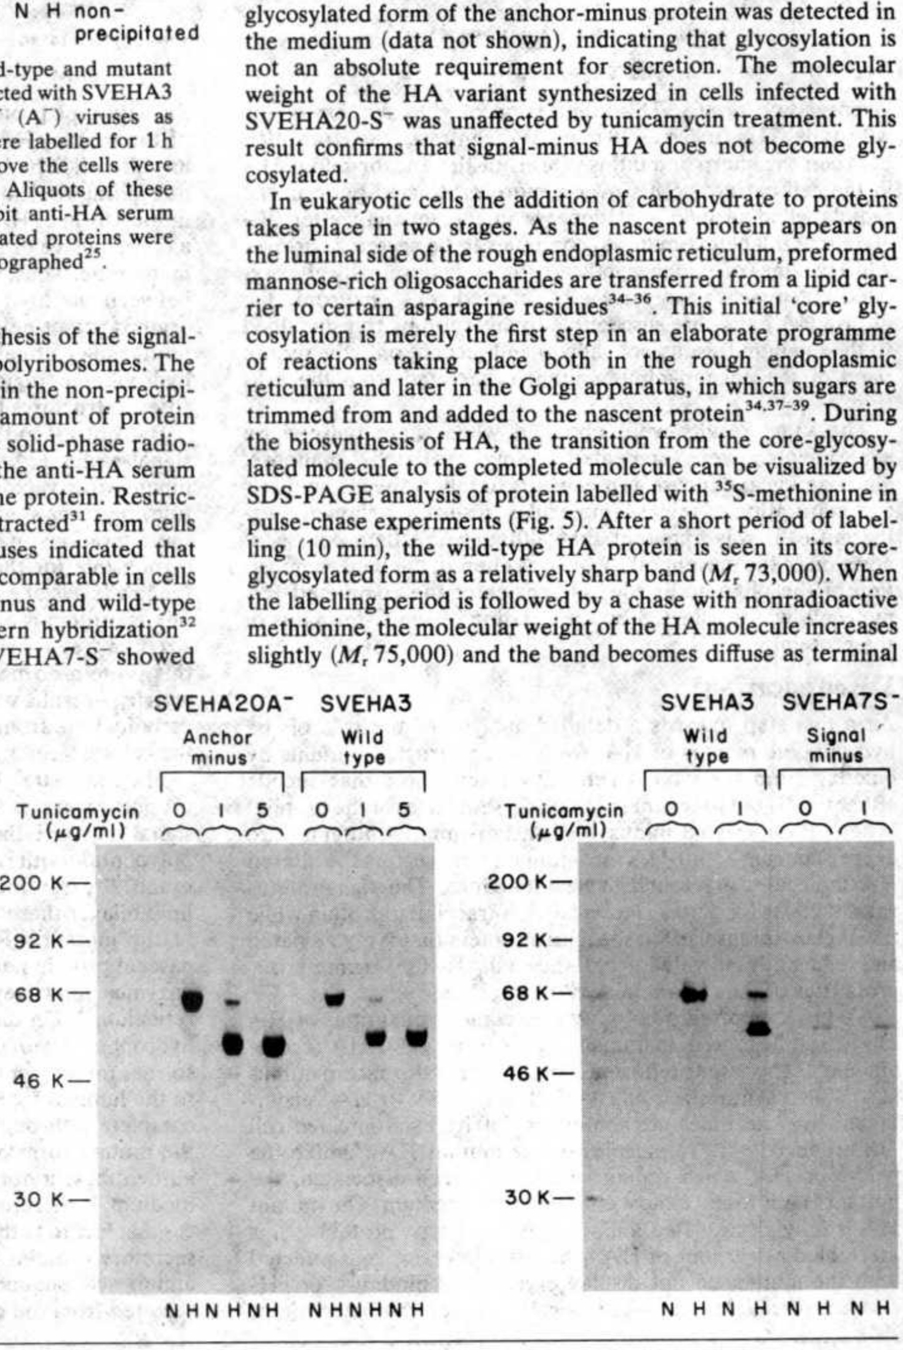
mRNA[25]. This result is consistent with synthesis of the signal-minus HA as a cytoplasmic protein on free polyribosomes. The failure to detect a major band of M_r 61,000 in the non-precipitated sample indicates that the decreased amount of protein observed both in this experiment and in the solid-phase radioimmunoassay is not due to the inability of the anti-HA serum to recognize the non-glycosylated form of the protein. Restriction endonuclease analysis of viral DNA extracted[31] from cells infected with the various recombinant viruses indicated that the numbers of recombinant genomes were comparable in cells infected with the anchor-minus, signal-minus and wild-type SV40-HA recombinants. However, Northern hybridization[32] of RNA purified from cells infected with SVEHA7-S⁻ showed that the level of HA-specific sequences was several-fold lower than in cells infected with the other recombinants. Furthermore, experiments in which infected cells were labelled for short times with ^{35}S-methionine and then chased showed that the signal-minus HA was more rapidly degraded than the wild-type protein. Taken together, these results indicate that the low yield of signal-minus HA may be due to instability of both the mutant mRNA and its protein product.

Analysis of glycosylation of HA mutants

To ascertain whether the various HA species were glycosylated, infected cells were labelled with ^{35}S-methionine in the presence of tunicamycin, a drug that blocks the formation of the dolichol-oligosaccharide donor and thus prevents primary glycosylation of the nascent polypeptide[33]. SDS-PAGE analysis of the resulting proteins is shown in Fig. 4. Tunicamycin treatment of cells infected with SVEHA3 or SVEHA20-A⁻ resulted in a reduction in the sizes of the immunoprecipitated proteins to M_rs of 61,000 and 58,000, respectively. These sizes are the same as those of the non-glycosylated forms of the protein synthesized *in vitro* by translation of wild-type and anchor-minus HA mRNA (data not shown). A small proportion of the non-glycosylated form of the anchor-minus protein was detected in the medium (data not shown), indicating that glycosylation is not an absolute requirement for secretion. The molecular weight of the HA variant synthesized in cells infected with SVEHA20-S⁻ was unaffected by tunicamycin treatment. This result confirms that signal-minus HA does not become glycosylated.

In eukaryotic cells the addition of carbohydrate to proteins takes place in two stages. As the nascent protein appears on the luminal side of the rough endoplasmic reticulum, preformed mannose-rich oligosaccharides are transferred from a lipid carrier to certain asparagine residues[34-36]. This initial 'core' glycosylation is merely the first step in an elaborate programme of reactions taking place both in the rough endoplasmic reticulum and later in the Golgi apparatus, in which sugars are trimmed from and added to the nascent protein[34,37-39]. During the biosynthesis of HA, the transition from the core-glycosylated molecule to the completed molecule can be visualized by SDS-PAGE analysis of protein labelled with ^{35}S-methionine in pulse-chase experiments (Fig. 5). After a short period of labelling (10 min), the wild-type HA protein is seen in its core-glycosylated form as a relatively sharp band (M_r 73,000). When the labelling period is followed by a chase with nonradioactive methionine, the molecular weight of the HA molecule increases slightly (M_r 75,000) and the band becomes diffuse as terminal

Fig. 4 Effect of tunicamycin on the HA proteins expressed from wild-type and mutant genes. Monolayers of CV-1 cells, infected with the recombinant vectors as described previously[25], were treated with tunicamycin (0, 1 or 5 μg ml⁻¹ in DME containing 10% serum) between 46 and 48 h after infection. The cells were then labelled with ^{35}S-methionine in the presence of the same concentrations of tunicamycin. Cell extracts were prepared, immunoprecipitated, separated by SDS-PAGE and autoradiographed[25].



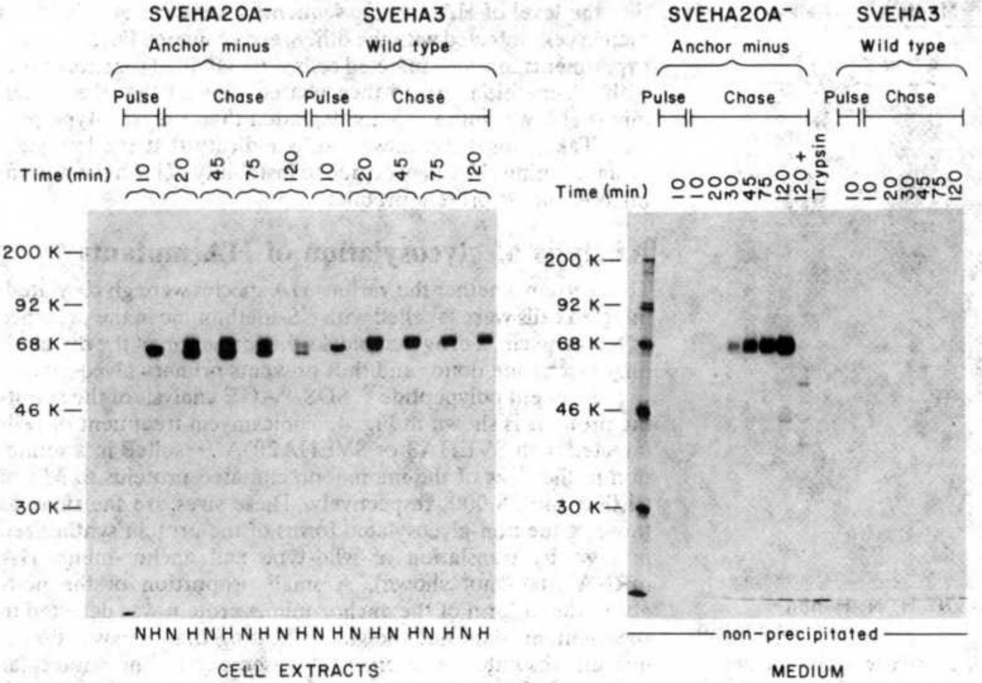


Fig. 5 Rate of processing of wild-type and anchor-minus HA glycoproteins. Monolayers of CV-1 cells were infected with SVEHA20-A⁻ or SVEHA3 viruses as described previously[25]. 48 h later the cells were labelled with ^{35}S-methionine[25] for 10 min. The monolayers were then washed twice with medium containing nonradioactive methionine and incubated at 37 °C in complete medium for further periods of time as shown in the figure. At each time point the supernatant medium was collected and cell extracts were prepared[25]. Aliquots of the cell extracts were immunoprecipitated using rabbit anti-HA serum (H) or normal rabbit serum (N). The precipitated proteins from the cell extracts, together with non-precipitated samples of the supernatant media, were separated by SDS-PAGE and autoradiographed[25].

glycosylation occurs. This completion of glycosylation of the wild-type HA takes ~20 min. By contrast, the transition between the sharp and diffuse forms of the anchor-minus HA in the cell extract occurs over a more protracted period. The radiolabelled protein first appears in the medium after 20–30 min and labelled material continues to be secreted for over 2 h. Two lines of evidence indicate that only terminally glycosylated HA reaches the surface of infected cells: first, only the diffuse HA bands are susceptible to digestion by trypsin added to the medium (results not shown) and second, only the diffuse band of the anchor-minus mutant is secreted from the cells (Fig. 5).

The same results were obtained when these pulse-chase experiments were repeated using tritiated mannose, glucosamine and fucose as precursors to follow the biosynthesis and maturation of the HA molecules (results not shown). Furthermore, it was apparent that although the time course of addition of the peripheral sugars was altered, the final composition of the oligosaccharide side chains of the completed HA molecule was unaffected by the deletion of the C-terminus of the protein.

Discussion

As a first step towards a detailed analysis of the role of the hydrophobic regions of HA, we have constructed mutants by deleting from the cloned gene DNA sequences that encode either the N- or C-terminal amino acid sequences of the protein. When these signal-minus or anchor-minus mutants are expressed from SV40-HA recombinant viral vectors the altered HA molecules are found in new locations. The signal-minus variant codes for a non-glycosylated, intracellular protein while the anchor-minus variant specifies a protein that is glycosylated and efficiently secreted from the cell. Table 1 summarizes properties of the mutant and wild-type HAs.

We have reported previously that copious quantities of HA can be synthesized in mammalian cells from SV40-HA recombinants[25]. The results reported here show that the anchor-minus HA is also synthesized efficiently from an SV40-HA recombinant. By late times after infection (60 h), each infected cell has produced $\sim 10^9$ molecules of the mutant HA. Unlike the wild-type HA which remains exclusively cell-associated, the mutant HA is found almost entirely in the medium. The mutant HA is fully glycosylated and, like the wild-type protein[17,18], is assembled as a trimer of HA subunits. However, cells infected with the mutant do not display erythrocyte binding[25] or *p*H-dependent cell fusion[23]—biological activities characteristic of the wild-type protein. From the predicted amino acid sequence of the mutant HA there would be no reason to suppose that any alteration had occurred in the structure or function of either its binding site[17] or of its fusion peptide[17,40]. The failure of the mutant form of HA to display these functions is almost certainly a consequence of its never being an integral part of the plasma membrane. Thus, the protein cannot form the necessary bridge between the lipid bilayer of the infected cell and that of the erythrocyte or neighbouring cell. Finally, the secreted HA has no haemagglutinating activity because, lacking the C-terminal hydrophobic region, the protein cannot aggregate to form rosette structures that bind erythrocytes polyvalently.

By contrast to the wild-type and anchor-minus proteins, the signal-minus HA is expressed at low levels from the recombinant virus vector (10^6 molecules per cell at 60 h post-infection). Further studies are underway to determine in what way the alterations in sequence at the 5′ end of the gene may be responsible for the instability of the mutant mRNA. Despite the low levels of expression, our results indicate that the signal-minus protein is an intracellular form of HA probably synthesized on free polyribosomes in the cytoplasm. Cells expressing this protein do not display erythrocyte binding or cell fusion activity—results which are consistent both with the absence of carbohydrate from the molecule[41] and with its failure to reach the cell surface.

The most straightforward explanations of the two mutants' properties are as follows. In the absence of the N-terminal signal sequence there can be no interaction of the nascent HA polypeptide with receptors on the endoplasmic reticulum membrane[42,43]; translocation of the growing polypeptide across the lipid bilayer therefore cannot occur. Consequently, translation of the mutant mRNA takes place in the cytoplasm and the nascent protein never comes into contact with the glycosylating enzymes that reside in the lumen of the endoplasmic reticulum[34]. On the other hand, the removal of the C-terminal hydrophobic sequence results in a loss of anchoring function, so that the nascent polypeptide, instead of remaining attached to the luminal face of the rough endoplasmic reticulum, passes completely through the membrane. Once free in the lumen, the mutant form of HA is treated by the cell as if it were an authentic secretory protein, and it is discharged into the medium. It therefore follows that apart from the signal sequences that facilitate their transport into the endoplasmic reticulum, secretory proteins as a class do not contain additional specific amino acid sequences that confer on them the ability to be secreted from the cell.

It is generally assumed that all secretory and integral membrane proteins are transported in vesicles from their site of synthesis on the endoplasmic reticulum via the Golgi apparatus to the plasma membrane. However, it is not known whether the two types of protein are sequestered into different vesicles or whether they follow exactly the same intracellular route. Although the number of proteins studied remains small, it appears that in general secreted proteins move more slowly than membrane proteins to the cell surface and that most, if not all, of this difference in rate arises in the part of the intracellular pathway between the endoplasmic reticulum and the Golgi apparatus[44]. Our results indicate that the transport of the two forms of HA also conforms to this pattern. Thus, by contrast to the membrane-bound wild-type protein which is glycosylated rapidly and relatively synchronously, the population of secretory molecules becomes terminally glycosylated over a very protracted period. It is possible that this difference in some measure reflects the relative efficiency with which membrane-bound proteins and luminal proteins are sequestered into the transport vesicles that travel from the rough endoplasmic reticulum to the Golgi apparatus. Even though the rate of glycosylation of anchor-minus HA is comparatively slow, the composition of the oligosaccharides attached to the wild-type and anchor-minus forms of the protein are not significantly different. It therefore appears that both the secreted and membrane-bound forms of the protein undergo the same sequence of modification reactions during their passage through the Golgi apparatus, and that the signals governing the pattern of glycosylation of HA cannot reside in the 38 amino acids that normally comprise the C-terminus of the protein.

While the mutant forms of HA have been artificially created *in vitro* by deleting portions of the gene, natural counterparts of these variants are found in eukaryotic cells. *Saccharomyces cerevisiae* produces, from a single gene, distinct mRNA species that code for secreted and cytoplasmic forms of invertase[45]. The secreted enzyme, which is glycosylated, is derived from a precursor that carries a 19-residue N-terminal signal sequence. By contrast, the cytoplasmic form of the enzyme is neither glycosylated nor derived from a precursor. In murine lymphocytes a single gene codes for both membrane-bound and secreted forms of immunoglobulin heavy chains[10,46,47]. Developmentally regulated alternative pathways of RNA processing give rise to either of two mRNAs, one of which encodes the secreted protein with a hydrophilic C-terminus, while the second encodes in addition a hydrophobic extension that anchors the protein in the membrane.

Finally, the studies with HA can be extended in several ways. For example, the functions of the hydrophobic regions can be analysed in fine detail by creating smaller deletions, insertions and point mutations at particular sites within the cloned HA gene. It will also be possible to construct genes coding for chimaeric proteins, in which the various functional domains of one membrane protein are exchanged for those of another. In this way it can be determined if signal and anchor sequences can be interchanged between different membrane proteins. Meanwhile, the work already accomplished is an illustration of what may become a general method for obtaining with ease large quantities of purified eukaryotic membrane antigens for experimental analysis or vaccine production. (After this manuscript was submitted a paper was published by Sveda *et al.*[48] on a similar topic.)

Asymmetric ligand binding by haemoglobin

Gregorio Weber

Department of Biochemistry, University of Illinois, Roger Adams Laboratory, Urbana, Illinois 61801, USA

The asymmetry observed in the titration curve of haemoglobin with oxygen is possible only if the α-α and β-β subunit interactions change by different amounts on oxygenation. This necessary difference justifies the $\alpha_2\beta_2$ structure on functional grounds and its magnitude shows that haemoglobin function results from reversible oxygen binding to the β subunit.

THE binding of oxygen to haemoglobin is generally presented as a plot of the logarithm of the oxygen concentration against the number of ligands bound per protein molecule (Bjerrum plot). Allen, Guthe and Wyman[1] obtained as the condition of symmetry of this plot about the midpoint a relation between the four dissociation constants: $K_1K_4 = K_2K_3$, and observed that it required symmetric haem–haem interactions. They believed that departures from symmetry were probably

0028–0836/82/500603—05$01 00

Table 1 Relative oxygen dissociation constants, asymmetries and computed binding constraints (kcal mol^{-1}) of haemoglobin A

Condition	K_1	K_2	K_3	K_4	Λ	$\{\alpha_o\beta_j\}$	$\{\alpha_o\beta_i\}$	$\{\beta\beta\}$
Stripped[6]	55.2	14.7	5.82	1	+0.44	1.21	0.96	0.57
HB-ATP[6]	345	124	73	1	+3.26	2.00	0.68	2.01
Hb-DPG[6]	545	118	218	1	+3.85	3.24	0.38	2.32
Hb-IHP[5]	127	56	224	1	+4.59	3.24	−0.41	2.72
Hb in 0.1 M phosphate[7]	542	106	153	1	+3.40	3.05	0.55	2.09

Computation of constraints made under the assumptions: $\delta I = 0$; $\{\alpha\alpha\} = 0$, first order constraints (equation (14)). The later work of Tyuma *et al.*[3] agrees well with the data: stripped Hb, $\Lambda = 0.87 \pm 0.35$; DPG-Hb, $\Lambda = 4.99 \pm 0.45$; IHP-Hb, $\Lambda = 4.14 \pm 0.45$.

artificial, but Roughton *et al.*[2] showed that there was significant asymmetry in the titration curve and more recently Tyuma *et al.*[3] saw a very marked increase in asymmetry on addition of phosphoric effectors to stripped haemoglobin. It is the purpose of this article to relate the asymmetry of titration curves for any number of binding sites to the asymmetry in the functions describing the ligand distribution among the protein molecules, and to show that in haemoglobin these asymmetries necessarily require a considerable difference in the change in interaction energies in the α-α and β-β boundaries upon oxygenation.

Symmetry of ligand distribution and of titration curve

When a protein binds several ligands at sites of identical affinity the distribution of ligands among the protein molecules is the normal Bernoulli distribution[4]. If on average $\bar{n}$ ligands are bound per protein molecule at N possible sites, the fraction of protein molecules binding J ligands is

$$f_J(\bar{n}) = \binom{N}{J}(\bar{n}/N)^J(1-(\bar{n}/N))^{N-J} \qquad (1)$$

where $\bar{n}/N$ is the average probability of occupancy of a site. The plots of f_J against $\bar{n}$, which specify the ligand distribution as $\bar{n}$ increases from 0 to N are, in the case of the normal distribution, symmetric about $\bar{n} = N/2$ in the sense indicated by the equation

$$f_J(\bar{n}) = f_{N-J}(N-\bar{n}) \qquad (2)$$

The symmetry of the distributions that are obtained when the binding sites have arbitrary, rather than equal affinities for the ligand may be readily derived. The dependence of $\bar{n}$ upon the concentration of free ligand [X], in equilibrium with the bound species[4,5] is described by an equation of the form

$$\bar{n} = \sum_{J=0}^{N} J\phi_J([\mathrm{X}]) \Big/ \sum_{J=0}^{N} \phi_J([\mathrm{X}]) \qquad (3)$$

$$\phi_J([\mathrm{X}]) = \binom{N}{J} \frac{[\mathrm{X}]^J}{K_1K_2\ldots K_J} \qquad (4)$$

$K_J (1 \leq J \leq N)$ is the intrinsic dissociation constant of the PX_J complex into the components X and PX_{J-1}. The dependence of the distribution of ligands upon [X] is given by

$$f_J(\bar{n}) = \phi_J([\mathrm{X}]) \Big/ \sum_{J=0}^{N} \phi_J([\mathrm{X}]) \qquad (5)$$

Let

$$\sum_{J=0}^{N} \phi_J([\mathrm{X}_{\bar{n}}]) \equiv P_{\bar{n}}; \quad K_1 \ldots K_J \equiv a_J \qquad (6)$$

where $[\mathrm{X}_{\bar{n}}]$ corresponds to an equilibrium with $\bar{n}$ bound ligands. Then equation (2) gives

$$\frac{[\mathrm{X}_{\bar{n}}]^J}{[\mathrm{X}_{N-\bar{n}}]^{N-J}} \frac{a_{N-J}}{a_J} = \frac{P_{\bar{n}}}{P_{N-\bar{n}}} = \frac{[\mathrm{X}_{\bar{n}}]^{J+1}}{[\mathrm{X}_{N-\bar{n}}]^{N-J-1}} \frac{a_{N-J-1}}{a_{J+1}} \qquad (7)$$

which reduces to

$$[\mathrm{X}_{\bar{n}}][\mathrm{X}_{N-\bar{n}}] = K_{N-J}K_{J+1} \qquad (8)$$

Equation (8) shows that a plot of log [X] against $\bar{n}$ symmetric about $N/2$ implies a ligand distribution which is also symmetric about $N/2$. Explicit knowledge of the dissociation constants is unnecessary to demonstrate the symmetry of ligand distribution, the constancy of the product $[\mathrm{X}_{\bar{n}}][\mathrm{X}_{N-\bar{n}}]$ being alone required. Further, equation (8) implies that if the ligand distribution is symmetric about $N/2$, products of pairs of the dissociation constants are equal. The ligand distribution for $N = 2$ is always symmetric. For $N = 3$ equation (9) gives

$$K_3K_1 = K_2^2 \qquad (9)$$

and for $N = 4$

$$K_2K_3 = K_1K_4 \qquad (10)$$

Figure 1 shows plots of log $[\mathrm{X}_{\bar{n}}][\mathrm{X}_{4-\bar{n}}]$ against $\bar{n}$ for two systems, with $N = 4$ and $K_4/K_1 = 43$. K_3K_2/K_1K_4 has been made equal to 4.59 and 1/4.59. Starting from the same point at $\bar{n} = 0$ the plots diverge towards values respectively larger and smaller than the initial one and tend to a constant value as $\bar{n}$ approaches 2. The asymmetry is seen to be of opposite nature according to whether K_4K_1 is smaller or larger than K_2K_3. To indicate the character and magnitude of the binding asymmetry I shall use the quantity

$$\Lambda = \ln(K_2K_3/K_1K_4) \qquad (11)$$

The choice of the logarithm ensures that reciprocal values of the ratio of products of constants are represented by the same figure with opposite sign and reserves $\Lambda = 0$ for the symmetric case. As shown in the figure the logarithmic increment

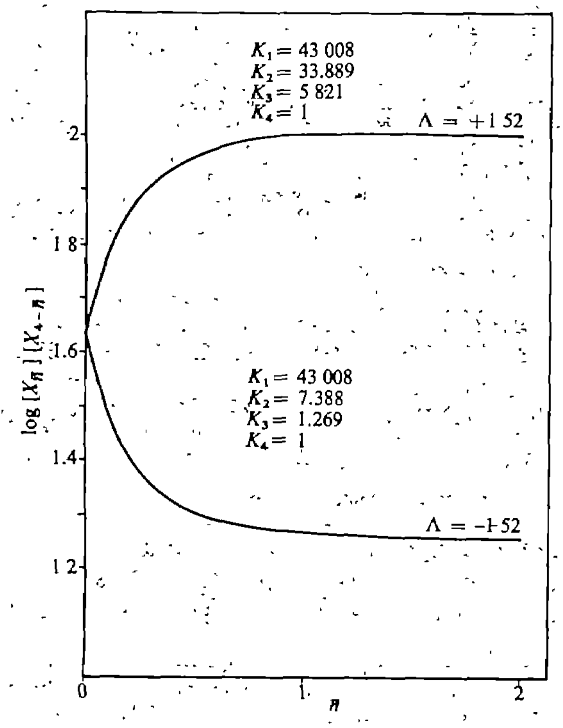

Fig. 1 A plot to demonstrate the opposite effects of negative and positive asymmetry of binding upon the titration curve.

for the positive asymmetry is the same as the logarithmic decrement for the negative one. The significance of positive versus negative asymmetry is disclosed in Fig. 2 which shows plots of f_J against $\bar{n}$ for the systems of Fig. 1. It is a general property of the distributions specified by equation (3) that f_J reaches a maximum at $\bar{n} = J$, whether the distribution is symmetric or otherwise. It is apparent from the figure that in the positive asymmetry the distribution is skewed so that $f_1(1) > f_3(3)$, while for the negative asymmetry the opposite obtains: $f_1(1) < f_3(3)$. Both distributions shown on Fig. 2 have equal Hill coefficients at $\bar{n} = 2$ of ~ 2.4. The result of the skewing towards f_1 in positive asymmetry is that the cooperative character of the binding is retained at values of $\bar{n}$ closer to 4 in comparison with the negative asymmetry, which exhibits the larger cooperativity at $\bar{n} < 1$. Consequently a smaller decrease in ligand concentration is required to produce the same unloading of X from the protein with positive asymmetry, at values of $\bar{n}$ close to 4. This is clearly shown in the Bjerrum plots of Fig. 3. On this basis alone one expects haemoglobin, which physiologically operates within the saturation range of 0.75 and 0.99+ to exhibit positive asymmetry. If the function of haemoglobin was to scavenge oxygen rather than to work as an almost saturated carrier a negative binding asymmetry would be beneficial to its function.

Origin of the asymmetric ligation

"When effects are asymmetric, the asymmetry should be apparent in their causes", said Pierre Curie in 1893[6]. To explain the origin of the asymmetry we take as an example a tetramer of the type $\alpha_2\beta_2$. This will permit direct application to haemoglobin, the only protein aggregate for which structure and properties are known in sufficient detail to permit this kind of analysis. In an $\alpha_2\beta_2$ tetramer there are six possible subunit interactions: of these the interactions at $\alpha_1\beta_1$ and $\alpha_2\beta_2$ and those at $\alpha_1\beta_2$ and $\alpha_2\beta_1$ respectively equal because of the structural symmetry, so that there are only four different interactions that we shall call $\alpha_i\beta_i$, $\alpha_i\beta_j$, $\alpha\alpha$ and $\beta\beta$. To lighten the notation we designate as $\bar{\alpha}$ and $\bar{\beta}$ the Gibbs free energy changes on binding of dioxygen to the subunits, in the absence of changes in subunit interactions, and we designate as $\{\alpha_i\beta_i\}$, $\{\alpha_i\beta_j\}$, $\{\alpha\alpha\}$, $\{\beta\beta\}$ the difference in free energy of the intersubunit binding between unliganded and fully liganded haemoglobin. These differences have the opposite sign to the free energies of binding, if they are binding constraints, and a wealth of observations indicate that in haemoglobin the subunit interactions operate as binding constraints. To compute the effects that may be expected upon ligation it is necessary to specify how the constraints disappear as successive units are liganded and to this purpose we distinguish two possibilities: a first order constraint, which disappears when a subunit at either side of the boundary is liganded, and a second order constraint, which disappears only when the two subunits across the boundary are liganded. Constraints of the third or fourth order may indeed exist but they must have a very secondary importance in relation of those of first or second order and we neglect them in our treatment. The insignificance of constraints of order intermediate between the first and the second will be made clear shortly.

Computation of the binding asymmetry

The Gibbs free-energy levels $G_0, G_1, \ldots, G_4$, corresponding to the species P, PX, ..., PX_4 respectively, are related to the dissociation constants appearing in equation (4) by the equation:

$$\ln K_j = \frac{1}{RT}(G_j - G_{j-1}) \qquad 1 \leqslant j \leqslant 4 \tag{12}$$

If the free-energies are expressed in RT units, as we shall do in the following, RT disappears in the last and all subsequent equations involving the G values and the binding asymmetry expressed as a function of them is, from (11) and (12)

$$\Lambda = G_0 - 2G_1 + 2G_3 - G_4 \tag{13}$$

which shows that computation of Λ does not require the explicit value of G_2. The contribution to the chemical potentials resulting from the interaction of two binding sites is always expressible as a free-energy coupling between them[7]. Binding constraints are antagonistic free energy couplings between the binding of one subunit by another and the binding of either to the ligand. The constraints present when possible sets of sites are liganded are recorded below, where $S = \{\alpha_i\beta_i\} + \{\alpha_i\beta_j\}$

Ligands bound	C (sites filled)	1st order value	2nd order value	
0	C_0	$2S+\{\alpha\alpha\}+\{\beta\beta\}$	$2S+\{\alpha\alpha\}+\{\beta\beta\}$	
1(α)	C_α	$S+\{\beta\beta\}$	C_0	
1(β)	C_β	$S+\{\alpha\alpha\}$	C_0	
2($\alpha\alpha$)	$C_{\alpha\alpha}$	$\{\beta\beta\}$	C_0-$\{\alpha\alpha\}$	
2{$\beta\beta$}	$C_{\beta\beta}$	$\{\alpha\alpha\}$	C_0-$\{\beta\beta\}$	
2($\alpha_i\beta_i$)	$C_{\alpha_i\beta_i}$	$\{\alpha_i\beta_i\}$	C_0-$\{\alpha_i\beta_i\}$	(14)
2($\alpha_i\beta_j$)	$C_{\alpha_i\beta_j}$	$\{\alpha_i\beta_j\}$	C_0-$\{\alpha_i\beta_j\}$	
3($\alpha\alpha\beta$)	$C_{\alpha\alpha\beta}$	0	$S+\{\beta\beta\}$	
3($\alpha\beta\beta$)	$C_{\alpha\beta\beta}$	0	$S+\{\alpha\alpha\}$	
4	C_4	0	0	

The contribution to the Gibbs levels from each ligand configuration of the table amounts to

$$G(\alpha, \beta) = C(\alpha, \beta) + k\bar{\alpha} + m\bar{\beta} \tag{15}$$

where $0 \leqslant k, m \leqslant 2$; $k + m = j$.

Some of the Gibbs levels are manifolds and the contributions of equation (15) must be weighted[4] to obtain the average value. For G_1 and G_3 the weights are:

$$f_\alpha = \exp(C_\alpha + \bar{\alpha})/(\exp(C_\alpha + \bar{\alpha}) + \exp(C_\beta + \bar{\beta})) = 1 - f_\beta \tag{16}$$

$$f_{\alpha\alpha\beta} = \exp(C_\alpha + 2\bar{\alpha} + \bar{\beta})/(\exp(C_\alpha + 2\bar{\alpha} + \bar{\beta}) + \exp(C_\beta + \bar{\alpha} + 2\bar{\beta})) = 1 - f_{\alpha\beta\beta} \tag{17}$$

With the constraints of (14), (13) gives, for first order constraints

$$\Lambda_1 = 2(\bar{\alpha} - \bar{\beta})[f_{\alpha\alpha\beta} - f_\alpha] - [\{\alpha\alpha\} - \{\beta\beta\}](2f_\alpha - 1)$$

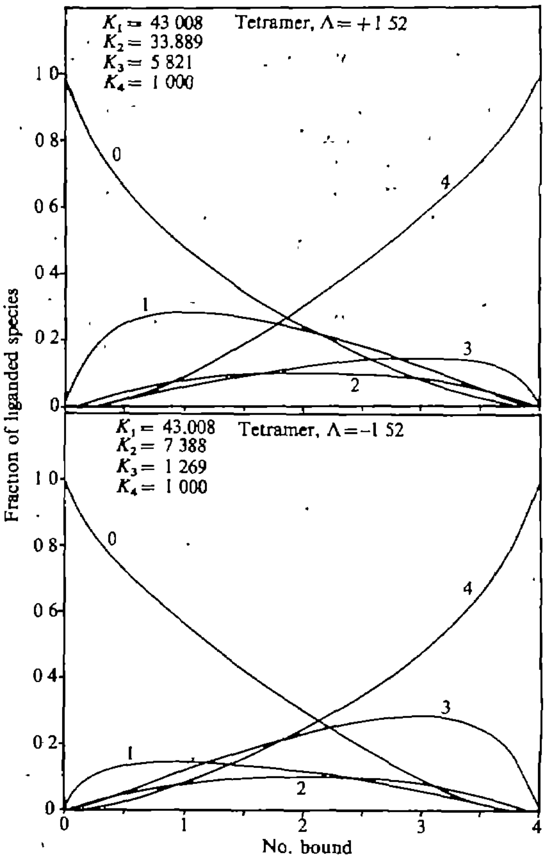

Fig. 2 Skewing in opposite senses of the distribution of ligands for the tetramers of Fig. 1. Numbers on the curves are J values.

and for second order constraints,

$$\Lambda_2 = 2(\bar{\alpha} - \bar{\beta})[f_{\alpha\alpha\beta} - f_\alpha] + [\{\alpha\alpha\} - \{\beta\beta\}](2f_{\alpha\alpha\beta} - 1) \quad (18)$$

and with the substitutions $\delta I = \bar{\alpha} - \bar{\beta}$, $\delta D \doteq \{\alpha\alpha\} - \{\beta\beta\}$ and the f values of equations (16) and (17)

$$\Lambda_1 = \frac{(2\delta I + \delta D)e^{\delta I}(e^{\delta D} - 1) + \delta D(e^{2\delta I + \delta D} - 1)}{(1 + e^{\delta I})(1 + e^{\delta I + \delta D})} \doteq -\Lambda_2 \quad (19)$$

From the last equation,

$$\Lambda_1 = \Lambda_2 = 0 \quad \text{if } \delta D = 0 \quad (20)$$

Therefore, it is a necessary condition for asymmetric ligation, that $\delta D \neq 0$; the 'diagonal' intersubunit couplings $\{\alpha\alpha\}$ and $\{\beta\beta\}$, therefore, must be different. The difference in affinity of the α and β subunits cannot by itself give rise to asymmetry of ligation. If $\delta I = 0$

$$\Lambda_1 = -\Lambda_2 = \delta D \frac{(e^{\delta D} - 1)}{(e^{\delta D} + 1)} \quad (21)$$

and in this case Λ_1 is always positive and Λ_2 always negative. Figure 4 shows plots of Λ_1 and Λ_2 against δD for fixed values of δI. If δI and δD have the same sign Λ_1 is always positive, Λ_2 always negative. Λ_1 can be negative and Λ_2 can be positive if δI and δD have opposite signs and additionally $|\delta D| < |2\delta I|$, the inversion of sign taking place at the point $\delta D + 2\delta I = 0$. A difference in the intrinsic chemical affinity of the subunits can therefore combine with the difference in the value of the diagonal constraints to modulate the asymmetry and even change its sign. From the plots in Fig. 4, as well as from intuitive considerations, one expects that for constraints of the order of 1.5, that is when ligation at the two sides of the boundary decreases the constraints by equal amounts, all asymmetry should disappear, and this can be easily proved by calculating the value of Λ for this case using the method used to derive the values of Λ_1 and Λ_2.

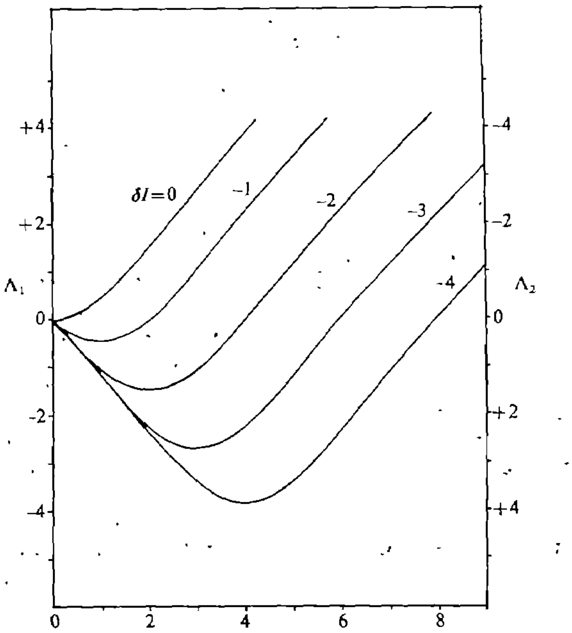

Fig. 4 Plots giving the asymmetry Λ as a function of δD for various values of δI (equation (19)). Λ_1, scale for first order constraints; Λ_2, scale for second order constraints.

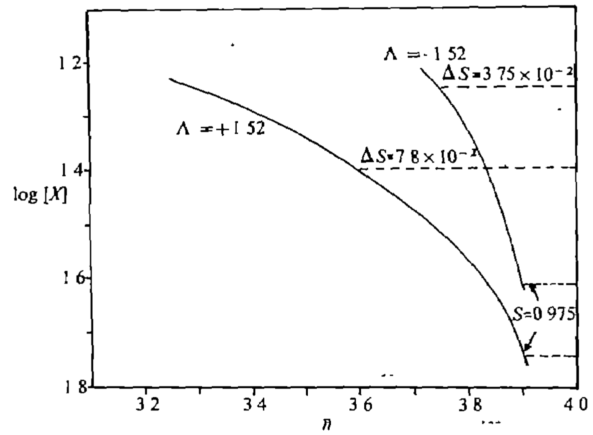

Fig. 3 Differences in the last portion ($\bar{n} > 3.2$) of the Bjerrum plots of the tetramers of Fig. 1, showing the difference in change in saturation (ΔS) for the same increment in free-ligand concentration ($\Delta \log X$).

Application to haemoglobin

The dissociation constants for the four steps of the reaction with oxygen have been determined by Tyuma and coworkers[8,9] for stripped haemoglobin and for the complexes of haemoglobin with diphosphoglycerate (DPG), adenosine triphosphate (ATP) and inositolhexaphosphate (IHP). Knowles and Gibson[10] determined them in the course of a detailed study of the equilibrium of oxygen with haemoglobin in 0.1 M phosphate solutions. All these studies, summarized in Table 1, indicate a high degree of positive asymmetry for the solutions in phosphate or phosphoric esters and a still positive, though clearly a much smaller one for stripped haemoglobin. The increase in positive asymmetry on addition of DPG is no small effect that requires the exact determination of the dissociation constants for its verification. It is evident in the Bjerrum plots of Fig. 3 of the early paper of Benesch *et al.*[11] and in the Hill plots of Fig. 3 of the paper of Tyuma *et al.*[9]. A glance at Fig. 4 indicates that an asymmetry of +3.5 to +4.5 requires a very large difference in the affinities of the α and β chains if the binding constraints are of second order, but a small or null value of δI if the constraints are of the first order. The difference in affinity of the chains is smaller than 1 RT according to Brunori *et al.*[12], and on these grounds it seems safe to conclude that the binding constraints operative in haemoglobin are first order constraints. In calculating the binding constraints from the dissociation constants we found it expedient to set $\delta I = 0$, because the small difference in oxygen affinity of the isolated chains would result in only a minor increase—smaller than 20%—in the value of δD required to satisfy a given asymmetry. Because of the negligible $\alpha\alpha$ boundaries we additionally set $\{\alpha\alpha\} = 0$ or $|\delta D| = \{\beta\beta\}$. With these assumptions the value of the $\{\beta\beta\}$ constraint may be calculated from the asymmetry by means of equation (21) or estimated with acceptable accuracy from the plots of Fig. 4. The total value of the constraints equals the difference between the free energy of binding of the four ligands in the actual system and the free energy of binding to four unconstrained sites:

$$G_4 - G_0 - 4 \ln K_4 = \ln (K_1 K_3 K_2 / K_4^3) = 2S + \{\beta\beta\} \quad (22)$$

The separate symmetric constraints can be determined by fitting the values of G_0 to G_4 to satisfy the experimental quantities. From independent, mainly structural, evidence[13] we assigned the larger of the two values to the $\alpha_1\beta_1$ boundaries (Table 1). While we dare not make an estimate of the uncertainty of the derived constraints, there is no reason to doubt the validity of the general trends. The $\{\beta\beta\}$ constraint increases systematically in the order: stripped Hb < ATP-Hb < PO_4-Hb < DPG-Hb < IHP-Hb, in agreement with observations that indicate the cross-linking of the isolated β chains by IHP[14]. The symmetric constraints are affected in opposite directions by the increase in the $\beta\beta$ constraint. The value of $\alpha_1\beta_1$ increases, but that of $\alpha_1\beta_1$ decreases to the point that in the IHP complexes this boundary is stabilized, not weakened by ligation. Evidently we are far from the simplicity of two-state models. The recent analysis of mutants of haemoglobin has led Pettigrew *et al.*[15] to conclude, with good evidence, that the $\alpha_1\beta_1$ boundary provides the main constraint to binding and is responsible for the greater part of the cooperativity. This conclusion is supported by the data of

Table 1, which, however, indicates that other constraints, particularly the asymmetric one must play a part. An estimation of the binding asymmetry of mutant haemoglobins seems highly desirable.

I shall end by pointing out those aspects of the function of haemoglobin that can only be adequately explained by reference to asymmetric ligand binding. One is the exclusive correlation of the asymmetry with the diagonal constraint, while the greater part of the affinity and cooperative behavior are determined by the symmetric constraints. This separation of functions in different regions of the molecule entails their independence in physiological control and genetic selection. An α_4 tetramer could not be expected to exhibit differences in the diagonal constraints so that the structure of haemoglobin as an $\alpha_2\beta_2$ tetramer appears now justified on functional grounds. To our knowledge no satisfactory reason for this structure has been previously offered.

In haemoglobin the asymmetry increases in the order: stripped Hb < ATP-Hb < PO_4-Hb < DPG-Hb < IHP-Hb, indicating by itself the importance of this property in the molecular adaptation to lower oxygen pressures. The role of the effector in these cases has been seen as one of reducing the affinity for oxygen but some place must be given to the increase in positive asymmetry as this results in a larger unloading of oxygen for the same decrease in partial oxygen pressure. In the absence of differences in the intrinsic ligand affinities of the α and β chains preferential binding to either chain can only take place if there is appreciable asymmetric binding. At the values of Λ of stripped haemoglobin there can only be a slight precedence of α over β in the order of binding, but this precedence will rapidly increase with the $\beta\beta$ cross-linking by the phosphoric effectors. At the asymmetry reached with IHP almost complete precedence of α over β may be expected so that the oxygen transport by haemoglobin will result, to a large extent from reversible binding to the β subunit. The work of Chien Ho and his collaborators[16,17] employing high resolution NMR substantiates this expectation. Considerations of binding asymmetry make clear why haemoglobin is not a suitable model for the regulatory properties of enzymes: haemoglobin works as an easily saturable carrier shuttling between 2/3 and full saturation while enzymes, working more often than not at substrate concentrations that result in modest degrees of ligation, would be expected to benefit from negative binding asymmetry. This could also be at the basis of the often reported partial, or half-of-sites, reactivity[18]. The importance of negative binding asymmetry in these and other cases must await a detailed analysis to be carried out with this precise question in mind.

Activation of a cellular oncogene by DNA rearrangement: possible involvement of an IS-like element

Gideon Rechavi, David Givol & Eli Canaani

Department of Chemical Immunology, Weizmann Institute of Science, Rehovot 76 100, Israel

The cellular oncogene c-mos *is rearranged in a mouse myeloma and the tumour mRNA contains transcripts hybridizing with a* v-mos *probe. The rearranged gene* (rc-mos) *was cloned in λ phage and shown to transform mouse fibroblasts in transfection assays.* rc-mos *differs from its progenitor,* c-mos, *only at the 5′ end of the gene, where* c-mos *sequences have been substituted by a novel cellular DNA fragment. This fragment contains a 159-base pair (bp) insertion sequence (IS)-like element localized immediately 5′ to the junction with* c-mos. *This is the first demonstration in a non-virally-induced tumour of activation of a cellular oncogene by a mechanism possibly involving DNA transposition.*

THE nature of the genetic events associated with the malignant transformation of normal cells in natural or induced conditions is little understood. Much of our knowledge of these events has come from studies of the rapidly transforming and slowly transforming retroviruses. It is now well established that the first group of viruses acquired their oncogenic properties by incorporating within their genomes one of a group of cellular *onc* (c-*onc*) genes[1,2] which are limited in number[3], evolutionarily conserved[4,5] and probably have an essential physiological role in the normal cell and organism. Once incorporated into the viral genome, the *onc* gene (now termed v-*onc*) is controlled by viral signals and expressed in abnormally elevated levels within the infected cell. It is also possible that the viral *onc* gene product differs in subtle but critical ways from its progenitor, the cellular gene. The slowly transforming retroviruses, which do not transduce cellular genes, were shown in some cases[6,7] to activate transcription of a particular cellular *onc* gene by integration in an adjacent position on the cellular DNA.

The situation is more obscure for the non-virally-induced tumours. By using the DNA-mediated gene transfer approach, it was possible to assay tumour DNAs for their ability to transform mouse fibroblasts in culture. This approach led to the identification of transforming genes in chemically- and radiation-induced tumours[8–12] and in spontaneous human and mouse tumours[9,10,13–16]. Recently, three transforming genes from human bladder carcinomas[17–19] and one human lung carcinoma[17] were identified as the activated forms of the normal human homologue of the viral *onc* genes Ha-*ras* and Ki-*ras*, respectively. Preliminary attempts using restriction enzyme mapping were unable to detect structural differences between the human transforming genes and their normal counterparts[18,19]. On the other hand, the association of chromosomal aberrations with many murine and human tumours suggested that DNA rearrangements might constitute a general mechanism for tumour induction[20], possibly by their effect on cellular oncogenes[21].

0028-0836/82/500607—05$01 00

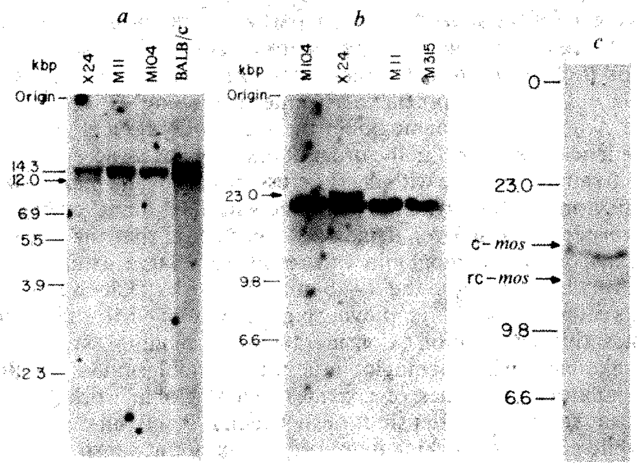

Fig. 1 Analysis of the c-*mos* gene in mouse myeloma DNAs. High molecular weight DNA from mouse myelomas MOPC104E, XRPC24, MPC11 and MOPC315 (referred to in the figure as M104, X24, M11 and M315, respectively) was digested with *Eco*RI (*a*) or *Bam*HI (*b*). Aliquots (20 µg) were electrophoresed on 0.7% agarose gels, blotted onto nitrocellulose filters and hybridized to the *Hin*dIII–*Bgl*I v-*mos*-specific fragment[23] radiolabelled by nick-translation. After hybridization, the blots were subjected to autoradiography. For molecular cloning, the c-*mos* and rc-*mos* *Eco*RI DNA fragments were enriched from XRPC24 DNA by electrophoresing 500 µg of digested DNA on 0.5% agarose gel, identifying the location of the two fragments on the gel by hybridization (*c*) and elution of the DNA by adsorption to glass beads[50]. Arrows indicate the rearranged band.

We undertook the present studies to search in non-virally-induced murine myelomas for the possible activation of another cellular oncogene, c-*mos*. This gene, which is the progenitor of the transforming information in Moloney murine sarcoma virus (M-MuSV)[22,23], was characterized extensively by transfection studies[23-25] and nucleotide sequencing analysis[26,27]. These studies established that the cellular information contained within the genome of M-MuSV (denoted v-*mos*), and presumably transduced out of the mouse genome during generation of this virus, consists of a long open reading frame of 369 codons. This sequence is joined in phase to a segment of five codons of viral helper sequence immediately 5′ to the v-*mos* region[26,27]. A 37,000-molecular weight (MW) protein identified within virus-infected cells[28] is presumably encoded by the 374-codons sequence and directly triggers cellular malignant transformation. The cellular homologue of v-*mos* (c-*mos*) contains 21 more codons joined in phase 5′ to the 369-codon open reading frame described above[27]. So far, no proteins encoded by this gene have been found in normal cells. Here we show that the c-*mos* gene is biologically activated in a particular mouse myeloma. The activation is due to DNA rearrangement at the 5′ end of the cellular gene, involving deletion of c-*mos* information and insertion of a small DNA fragment having structural properties characteristic of an IS element.

c-*mos* gene is rearranged and transcribed in a mouse myeloma

We screened the DNA of several BALB/c mouse myelomas by Southern blot analysis using the *Hin*dIII–*Bgl*I *src*-specific fragment of v-*mos*[23] as a probe; one of the tumours—XRPC24—showed an additional hybridizing band detected by this probe (Fig. 1). In the *Eco*RI digest, this additional band was smaller (12.5 kilobase pairs, kbp) than the 14-kbp c-*mos* band, whereas in the *Bam*HI digest the additional band was larger (23 kbp) than the 21-kbp c-*mos* band. These results indicated that the endogenous c-*mos* gene had undergone some rearrangement in the pristine-induced XRPC24 tumour, therefore we will refer to it as rc-*mos*. We attempted to determine whether this DNA rearrangement is associated with enhanced transcription of the gene. The poly(A)-containing RNA fraction was extracted from the same plasmacytomas and analysed by the Northern technique for *mos*-specific transcripts. Figure 2 shows that the probe detected a transcript of 1.2 kilobase (kb) in the RNA of myeloma XRPC24. No hybridization was observed with RNAs from the other tumours tested. Thus, the appearance of rc-*mos* DNA is correlated with increased transcription of the gene.

To compare c-*mos* and rc-*mos*, we cloned both genes from myeloma XRPC24 DNA digested with *Eco*RI. The 14-kbp and 12.5-kbp *mos* fragments were enriched by preparative agarose gel electrophoresis (see Fig. 1*c*) and cloned into Charon 4A λ phage vector[29]. Several clones containing one of the two inserts were purified and analysed in detail.

c-*mos* and rc-*mos* differ at the 5′ region

The two cloned genes were analysed by restriction enzymes; the partial physical maps are shown in Fig. 3. The restriction map of c-*mos* is identical to that published by Vande Woude and co-workers[25]. rc-*mos* shares with c-*mos* an identical 12-kbp fragment between the *Bgl*I site at 3.1 kbp on the map and the 3′ end of the insert. The two clones differ at the region 5′ to the *Bgl*I site up to the *Eco*RI site. The sequence of this region in the rc-*mos* clone, determined according to the strategy shown

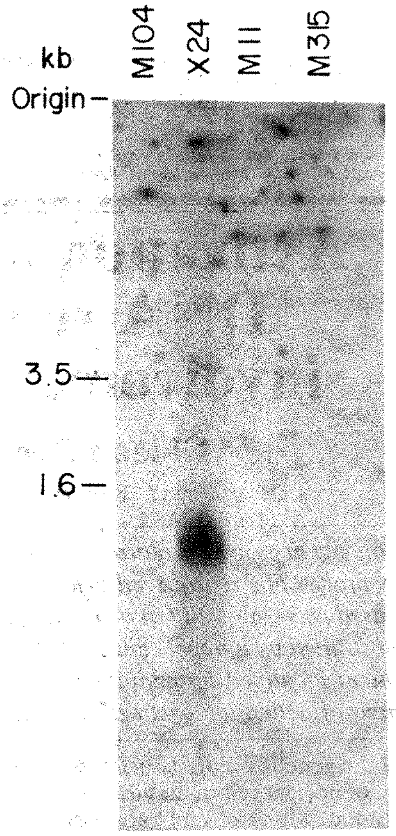

Fig. 2 Analysis of poly(A)$^+$ RNA from mouse myeloma for the presence of c-*mos* transcripts. Aliquots (50 µg) of poly(A)-selected RNA from myelomas MOPC315, MOPC104E, XRPC24 and MPC11 (M315, M104, X24, M11 in the figure) were heated at 60 °C for 10 min in a solution containing 50% formamide, 6% formaldehyde and running buffer (20 mM MOPS *p*H 7.0, 5 mM NaAc, 1 mM EDTA). The samples were electrophoresed at 100 V for 5 h in 1% agarose gel containing 6% formaldehyde and 1× running buffer. The RNA was transferred with 10×SSC to nitrocellulose filters, fixed by heating at 80 °C for 2 h and hybridized at 43 °C for 2 days to 2×10^6 c.p.m. ml^{-1} of v-*mos* probe in a solution containing 50% formamide, 5×SSC, 1×Denhardt's mixture, 20 mM sodium phosphate *p*H 7.0, and 100 $\mu\mathrm{g\,ml}^{-1}$ salmon sperm DNA. After washing at 50 °C with a solution of 0.1×SSC, 0.1% SDS, the filters were autoradiographed. Kb, kilobase.

in Fig. 3, is shown in Fig. 4 together with the corresponding published sequence of c-*mos*[27].

Clearly, rc-*mos* and c-*mos* are identical 3′ to nucleotide 513 and completely divergent 5′ of this point. The c-*mos* sequence deleted in the rearranged gene includes about one-quarter of the presumed c-*mos* coding sequence[27]. The deleted sequence also includes the first 41 codons in the portion of the gene shown to be conserved in both man and mouse[30]. The inserted novel DNA fragment contains an open reading frame of 28 codons which joins in phase the rest of the c-*mos* open reading frame at nucleotide 513 in the sequence shown in Fig. 4.

Unique structural features of the novel DNA sequences identified in rc-*mos*

Analysis of the rc-*mos* sequence immediately 5′ to the junction point (Fig. 4) showed the hexanucleotide CCAACA at positions 507–512. An almost perfect inverted repeat of this sequence—TGATTGG—was found 153 nucleotides upstream at positions 354–360. Further inspection of the sequence indicated that the 159-bp fragment terminated with the inverted repeats, is bound on both sides at positions 347–352 and 513–519 by the hexanucleotide, CACTCC, in a configuration of a direct repeat. As this hexanucleotide is part of the c-*mos* sequence, it must have duplicated during the insertion of the novel 159-bp fragment. Presumably, concomitant or subsequent to this insertion, c-*mos* sequences 5′ to the insertion point were deleted. The fragment encompassing the inverted and direct repeats can be drawn in a typical stem-and-loop configuration (see Fig. 5). It is remarkable that the 159-bp fragment ends with the dinucleotide TG…CA as do all eukaryotic movable elements[31–33], Mu phage[34,35] and retroviruses[36–38]. Finally, the 3′-terminal pentanucleotide of the fragment, CAACA, is identical to the 3′ terminus of the *Drosophila* transposable element *copia*[33], yeast Ty*1* mobile element[31,32], and spleen necrosis virus DNA[36].

Biological activity of the rearranged c-*mos* gene

Previously, it was shown that the molecularly cloned, 14-kbp c-*mos* gene was inactive when assayed for its ability to transform NIH 3T3 cells in transfection experiments[25]. To demonstrate biological activity of the gene, it was necessary to ligate a viral long terminal repeat (LTR) upstream from the 5′ end of the gene[25]. We asked whether the rearranged c-*mos* gene cloned from myeloma XRPC24 is active by itself when assayed by transfection; a typical experiment is shown in Table 1.

The two clones of the rc-*mos* gene that were tested induced a large number of foci having specific infectivities of 3,100 and 4,900 focus-forming units (FFU) per μg DNA, respectively (Table 1). In contrast, clones of the 14-kbp DNA fragment containing the normal c-*mos* gene showed negligible or no activity. As a positive control we used two recombinant phages containing integrated Moloney sarcoma viral DNA (E.C., unpublished) which produced 10,200 and 13,200 FFU per μg DNA (Table 1).

The cells transformed by rc-*mos* DNA were indistinguishable morphologically from those transformed with the viral genome. The transformants consisted of round and spindle-shaped highly refractile cells which grew in multilayers. The foci induced by rc-*mos* DNA could be detected 12 days after transfection in contrast to the 10 days required to detect the viral genome-induced transformants.

Conclusions

Here we have described a genetic event which led to the activation of a cellular *onc* gene in a non-virally-induced tumour. The normal c-*mos* gene has undergone DNA rearrangements in the murine myeloma XRPC24 and has become highly potent in transforming mouse fibroblast monolayers. The biological activation was associated with the appearance of c-*mos* gene transcripts in the tumour tissue. This is all the more notable as, unlike many cellular *onc* genes which are expressed in various normal and malignant cells[39–42], c-*mos* gene transcripts have not been detected previously in all cells examined[43]. The rearrangement of the gene was twofold: first, all sequences 5′ to position 513 (Fig. 4), including 263 nucleotides of the presumed coding sequence, were deleted; second, this information was substituted by a novel cellular DNA fragment. Within this fragment, the 3′-terminal 159-nucleotide sequence demonstrated several features (see Fig. 5) in common with bacterial IS elements[44,45], Mu phage[34,35], eukaryotic transposable elements[31–33] and retroviruses[36–38]: (1) Like all these elements, the sequence ends in a terminal inverted repeat. (2) The 3′-terminal two nucleotides, CA, and the 5′-terminal TG are common to all eukaryotic cellular movable elements, Mu phage and retroviruses. (3) The 3′-terminal five nucleotides, CAACA, are shared with the terminal sequence of yeast Ty*1* and *Drosophila copia* elements as well as with spleen necrosis virus DNA. (4) The sequence is bound on both sides by a direct repeat derived from c-*mos* DNA at the junction site. Similar short sequence duplications of the integration site are characteristic of all elements described above. Because of the small size of the sequence found here—159 bp—and the fact that it does not consist of two long terminal direct repeats, we consider the element to resemble most strongly bacterial IS elements or the Ty*1*-related solo δ units found in yeast[46]. Inspection of the sequence reveals neither transcription initiation and termination signals characteristic of retroviral long terminal repeats, nor any other homology to these viral sequences. By using hybridization methods, we detected no sequence homology between the DNA segment inserted 5′ to c-*mos* and Moloney murine leukaemia viral DNA. Moreover, our preliminary results indicate that although sequences within this DNA segment are present in normal mouse cell DNA in multiple copies, unlike endogenous murine retroviral sequences[47], they distribute in a highly conserved pattern in different mouse strains.

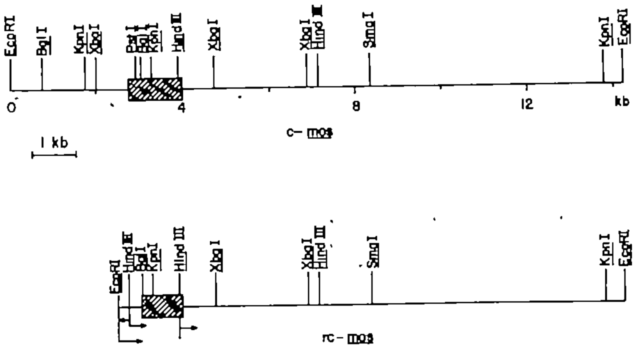

Fig. 3 Physical map of rc-*mos* and c-*mos*. The arrows indicate the strategy for DNA sequencing of rc-*mos*.

Table 1 Biological activity of molecularly cloned c-*mos* and rc-*mos* DNAs

Clone	Insert DNA (ng)	No. of foci	Specific infectivity (FFU per pmol DNA)
λ-MSV 26	50	150	10,200
λ-MSV 3-3	100	220	13,200
λ-c-*mos* IA	125	0	67
λ-c-*mos* IB	125	1	<67
λ-rc-*mos* 2B	100	43	3,100
λ-rc-*mos* 2F	100	68	4,900

Intact recombinant phage DNA was transfected into NIH 3T3 fibroblasts by the calcium phosphate method[49]. The cultures were kept in medium containing 5% fetal calf serum and were scored for focus formation 2 weeks after transfection. λ-MSV 26 and λ-MSV 3-3 represent M-MuSV molecules integrated within normal rat kidney cell DNA and molecularly cloned in λ Wes B vector. λ-c-*mos* and λ-rc-*mos* are molecular clones of the c-*mos* and rc-*mos* genes, respectively, obtained from XRPC24 myeloma DNA.

Fig. 4 Sequence of the novel DNA segment inserted into c-*mos*. The fragment encompassing the *Eco*RI–*Bgl*I region at the 5′ end of the rc-*mos* gene (Fig. 3) was sequenced according to Maxam and Gilbert[51]. Arrowed lines indicate the position of the direct (solid line) and inverted (broken line) repeats at the borders of the IS-like element. The c-*mos* sequence is shown for comparison, beginning with the first ATG of the open reading frame[27]. Amino acids translated from the DNA sequence are given in the single letter code. The junction between the novel DNA fragment and the c-*mos* sequence is indicated by a small arrow. The junction[26] between the viral helper DNA and the *mos* information within the M-MuSV genome (v-*mos*) is indicated by an open triangle. The sequence numbers are from the *Eco*RI site shown in Fig. 3.

Finally, note that the mechanism by which the DNA rearrangement took place is probably very complex. The removal of c-*mos* sequences 5′ to the insertion point suggests a process of insertion followed by deletion.

The mechanism by which the substitution of c-*mos* sequences with the new DNA fragment activated the gene is unclear. It is probable that the increased transcription of the gene is directly related to the change in its biological properties. It is also possible that the alterations in the structure of the putative protein encoded by the c-*mos* gene, had a rôle in the activation. It is tempting to speculate that the IS-like element inserted in the gene directly triggers the activation. The element could initiate transcription of the c-*mos* gene by introducing a strong promoter[48]. Alternatively, the presence of the element may lead to modifications of the chromatin structure at this site, which could create a putative promoter within the adjacent c-*mos* gene available for transcription. Analysis of the RNA transcripts, together with transfection studies using different DNA fragments, should elucidate the mechanism of activation.

The finding of a cell line synthesizing mRNA (and probably a transforming protein) encoded by the c-*mos* gene, albeit modified, provides the first opportunity of studying *in vivo* transcription of the cellular gene. The ability of the modified gene to transform suggests that the 263 nucleotides at the 5′ end of the c-*mos* gene as well as the 5′ 67 codons of v-*mos*, are dispensable for the transforming activity.

c-*mos* represents the third c-*onc* gene after Ha-*ras* and Ki-*ras*[17–19], shown to be activated in a non-virally-induced tumour. The modification here involved rearrangement at the 5′ end of the gene, including insertion of a 159-bp DNA fragment having the structure of an IS element. This is the first example of oncogene activation in a non-virally-induced tumour by a process of DNA transposition. Whether this is unique, or represents a general method of malignant conversion of potentially transforming cellular genes remains to be shown.

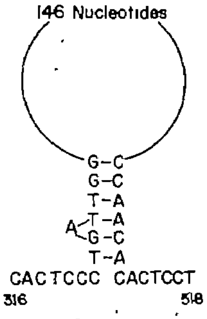

Fig. 5 Schematic representation of the IS-like element present at the rc-*mos* junction. Numbers are as in the nucleotide sequence given in Fig. 4.

We thank Mrs D. Ram, S. Wylder, M. Seiberg and A. Waisman for assistance. This work was supported in part by grants to E.C. from US–Israel Binational Science Foundation, from the Leukemia Research Foundation of Chicago, the Blum Foundation, and the Israel Cancer Research Fund.

Note added in proof: Rearrangement of cellular oncogenes might not be a very rare event, since we have now found that the c-*myc* gene has undergone rearrangements in several mouse plasmacytomas. In addition, we have recently obtained evidence for the rearrangement of the human c-*mos* gene in a particular Burkitt lymphoma line. In this case the rearranged c-*mos* gene was inserted near an immunoglobulin V_H gene. This rearrangement has probably resulted from the translocation of the end of chromosome 8, where human c-*mos* is located, to chromosome 14, where the human immunoglobulin heavy chain genes reside.

A DNA fragment containing the promoter of the mouse metallothionein-I gene fused to the structural gene of rat growth hormone was microinjected into the pronuclei of fertilized mouse eggs. Of 21 mice that developed from these eggs, seven carried the fusion gene and six of these grew significantly larger than their littermates. Several of these transgenic mice had extraordinarily high levels of the fusion mRNA in their liver and growth hormone in their serum. This approach has implications for studying the biological effects of growth hormone, as a way to accelerate animal growth, as a model for gigantism, as a means of correcting genetic disease, and as a method of farming valuable gene products.

THE introduction of foreign genes into mammalian embryos could form the basis of a powerful approach for studying gene regulation and the genetic basis of development. Recent studies have clearly established the feasibility of introducing foreign DNA into the mammalian genome by microinjection of DNA molecules of interest into pronuclei of fertilized eggs, followed by insertion of the eggs into the reproductive tracts of foster mothers[1–7]. The data suggest that the so-called transgenic animals that develop from this procedure integrate the foreign DNA into one of the host chromosomes at an early stage of embryo development. As a result, the foreign DNA is generally transmitted through the germ line[3,8,9]. In some cases, expression of these foreign genes has also been detected; low levels of rabbit β-globin and viral thymidine kinase (TK) activity were measured in transgenic mice after introducing the respective genes[6,7]. It is possible to obtain regulated expression of viral TK by fusing the structural gene to the mouse metallothionein-I (MT-I) gene promoter and inducing expression with heavy metals[2,9].

The possibility of introducing genes encoding secreted regulatory peptides into animals via this technology has several potential applications. The growth hormone (GH) gene whose protein product has profound developmental effects is particularly convenient for testing this possibility. Based on our success in achieving regulatable expression of herpes TK using the MT-I promoter[9], we fused this promoter to the rat GH structural gene which has been shown to direct GH synthesis in mouse cells[10]. We show here that when this gene construct (MGH) is introduced into eggs it is expressed efficiently, giving rise to greater than normal levels of growth hormone in transgenic mice. The most obvious consequence of this high level of growth hormone expression is gigantism. This success raises several issues of genetic and practical importance.

Generation of animals carrying MGH fusion genes

A fragment of the cloned rat GH gene, from which the 5′ regulatory region had been deleted, was fused to the MT-I promoter region, generating the plasmid pMGH (see Fig. 1*a*). In this construction, the fusion occurs in exon 1, retaining the initiation codon of the GH gene and the 5′ regulatory region of the MT-I gene. Thus, the fusion gene is predicted to direct transcription of a mRNA containing 68 bases contributed by MT-I, followed by 1 base contributed by an *Xho*I linker, then the rat GH mRNA sequence starting at nucleotide 7. This construction preserves the AUG initiation codon for GH synthesis located at position 124–126 (Fig. 1*c*), the four intervening sequences and the poly(A) site of the rat GH gene (Fig. 1*b*), and 3 kilobases (kb) of downstream chromosomal sequences.

A 5.0-kb fragment extending from the *Bgl*I site of MT-I (−185) to *Bam*HI (see Fig. 1*b*) was restricted from pMGH, separated from the other fragments on an agarose gel and used for injection into eggs. This linear fragment with heterologous ends was chosen because our recent experience suggests that such fragments integrate into host DNA more efficiently than supercoiled plsmids. Although this fragment contains only 253 base pairs (bp) of MT-I sequence, we have shown previously that this includes sequences essential for heavy metal regulation of the MT-I promoter[11,12]. The male pronuclei of fertilized eggs were microinjected with 2 pl containing ~600 copies of this fragment and 170 eggs were inserted into the reproductive tracts of foster mothers; 21 animals developed from these eggs[2].

When they were weaned, total nucleic acids were extracted from a piece of tail and used for DNA dot hybridization to

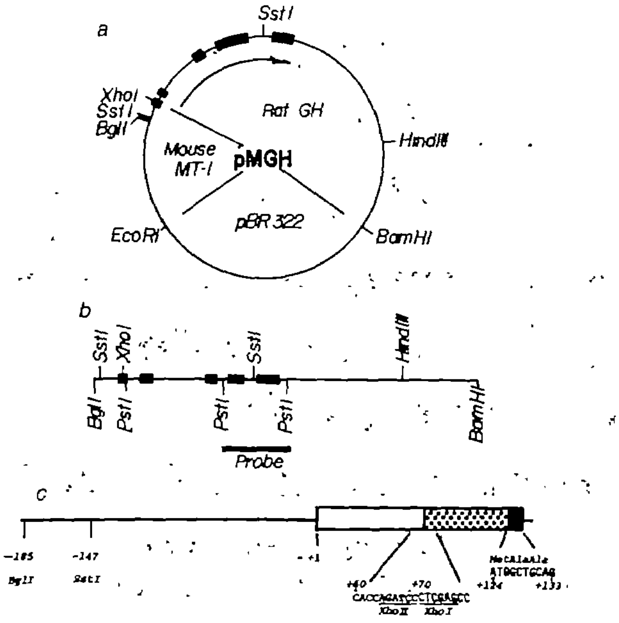

Fig. 1 Construction of the fusion plasmid pMGH. *a*, The unique *Bgl*II site of the MT-I genomic clone[28] was converted to a *Xho*I site by digesting with *Bgl*II, followed by filling in the sticky ends with Klenow fragment of DNA polymerase in the presence of all four dNTPs; then *Xho*I linkers (CCTCGAGG) were ligated to the blunt ends and bacterial strain RR1 was transformed with this DNA. The *Pvu*II site of pBR322 was converted to a *Bam*HI site by a similar procedure, then the 4.1-kb *Xho*I–*Bam*HI fragment containing the MT-I promoter and pBR was ligated to a 4.8-kb *Xho*I–*Bam*HI fragment containing the rat GH structural gene (see refs 10, 30) to give pMGH (8.9 kb). *b*, The fragment used for injection was a 5.0-kb *Bgl*I–*Bam*HI fragment which was isolated from an agarose gel by the NaClO$_4$ method[29]. For genomic Southern blots, a 1.0-kb *Pst*I fragment spanning exons 4 and 5 was isolated and nick-translated[9] and used as a hybridization probe. *c*, The predicted structure of exon 1 of the fusion gene. The line and open box represent MT-1 untranslated sequences, the stippled box represents GH untranslated sequences and the solid box represents the beginning of the GH coding region (see refs 28 and 30 for complete sequence information).

determine which animals carried MGH sequences. Seven of the animals gave hybridization signals above background (Fig. 2*a*) and their DNA was analysed further by restriction with *Sst*I and Southern blotting. This analysis showed that all seven had an intact 1.7-kb *Sst*I fragment predicted from the restriction map shown in Fig. 1. All the animals having a prominent 1.7-kb hybridizing band also revealed a 3.3-kb band. This band is predicted from a circularized version of the 5.0-kb *Bgl*I–*Bam*HI fragment. Two of the mice having multiple copies (MGH-10 and -19) gave a 5.0-kb hybridizing fragment when digested with *Hin*dIII, an enzyme that cuts only once within the injected fragment. Surprisingly, *Bam*HI also generates a 5.0-kb hybridizing fragment in all the DNAs analysed (MGH-10, -14, -16 and -19), suggesting that this restriction site was restored during circularization, whereas *Bgl*I and *Eco*RI (which does not cut within the fragment) gave larger fragments (data not shown). We conclude that all the MGH-positive animals have at least one intact *Bgl*I–*Bam*HI insert and four of the mice have a tandem head-to-tail duplication of this 5.0-kb fragment; however, the details of how and when this fragment circularized and integrated are not discernible. One of the mice, MGH-10, transmitted the MGH genes to half (10 of 19) of its offspring, suggesting that these genes are stably integrated into one of its chromosomes.

Rapid growth of mice carrying MGH genes

At 33 days post-parturition, all of the mice were weaned and maintained on a solid diet supplemented with water containing 5,000 p.p.m. ZnSO$_4$ (76 mM); their growth rate was recorded periodically. The dose of Zn was chosen on the basis of experiments which indicated that 5,000 p.p.m. induced almost maximal levels of MT-I mRNA in the liver without imparing the breeding potential of mice maintained on this diet for several months. Figure 3 shows the growth of the seven mice carrying MGH sequences. The littermates without MGH sequences served as convenient controls; the weights for each sex were averaged separately. Six of the mice with MGH sequences showed substantially more weight gain (up to 1.8-fold) than the controls. With the exception of MGH-16, there was a correlation between weight gain and MGH gene dosage (Table 1). The animal carrying the most copies of MGH sequences, MGH-21, died after 7 weeks of rapid growth; other mice have, however, grown larger. Most of the animals were already larger than normal before the Zn diet was instituted. Furthermore, one of the animals (MGH-19) was removed from the Zn diet on day 56 and it continued to grow at an accelerated rate. Thus, the effect of Zn on growth rate is uncertain. Perhaps mice carrying several copies of the MGH gene produce excess GH constitutively without a requirement for heavy metal induction. Thus, the question of Zn-dependent growth will be most easily answered by analysis of offspring of mice such as MGH-16 that contain only a few copies of the MGH gene.

Expression of the MGH gene in the liver

Based on previous studies with mice carrying metallothionein–TK fusion genes, maximal expression of MGH was expected in the liver, intestine and kidney. Evaluation of the tissue specificity of MGH gene expression was initiated by analysis of its activity in liver. A partial hepatectomy on day 56 allowed isolation and quantification of RNA for MGH-specific sequences. Figure 4*b* shows the results of RNA slot hybridization. The level of MGH mRNA expression in the liver correlated with the growth of the transgenic mice. The largest animals, MGH-2, -19 and -21, contained large amounts of MGH mRNA in the liver, whereas MGH-10, -14 and -16, which showed slower growth rates, contained ~50-fold less MGH RNA, not visible on the exposure shown in Fig. 4. Analysis of samples exposed to base hydrolysis before spotting the nucleic acids on to nitrocellulose (Fig. 4*a*) or treated with RNases A plus T$_1$ after hybridization (not shown) established that RNA rather than potentially contaminating DNA was hybridizing to the probe. From these data, we estimate that 30 μg of liver RNA from MGH-2, -19 and -21 contains the same amount of GH mRNA as 13, 25 and 50 ng of poly(A)$^+$ rat pituitary RNA,

Table 1 MGH genes, mRNA, GH levels, and growth of transgenic mice

Mouse	Sex	No. of MGH genes per cell	No. of MGH mRNA molecules per cell	Growth hormone (μg ml^{-1})	Growth* (g)	Ratio
MGH-2	♀	20	800	57.0	41.2	1.87
MGH-3	♀	1	<50	0.87	22.5	1.02
MGH-10	♂	8	<50	0.28	34.4	1.32
MGH-14	♂	2	<50	0.31	30.6	1.17
MGH-16	♂	2	<50	17.9	36.4	1.40
MGH-19	♂	10	1,500	32.0	44.0	1.69
MGH-21	♀	35	3,000	112.0	39.3	1.78
Female littermates (*n* = 3)		0	0	0.16 ±0.1	22.0 ±0.8	
Male littermates (*n* = 11)		0	0	0.15 ±0.08	26.0 ±2	

The number of MGH genes per cell was estimated by DNA dot hybridization and scintillation counting (Fig. 2*a*). MGH mRNA molecules per cell were estimated by densitometric scanning of the autoradiogram from RNA slot hybridization (Fig. 4) and assuming 2.5×10^5 mRNA molecules per liver cell. GH was measured by RIA as described elsewhere[10].

* Animal weights when 74 days old. The ratio of body weight compared with littermates of the same sex is indicated (see Fig. 3).

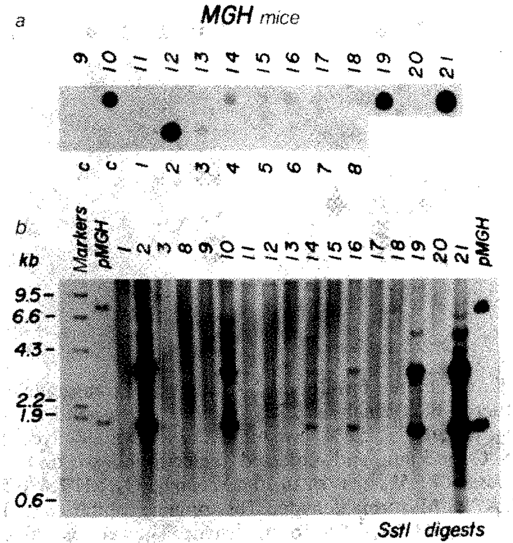

Fig. 2 Analysis of DNA from transgenic mice for MGH sequences. *a*, DNA dot hybridization[9] was used to detect mice with MGH sequences and quantitate their abundance. A nick-translated *Pst*I probe (see Fig. 1*b*) was used (6 h exposure). Numbers correspond to the MGH mice examined; c, controls. *b*, DNA (5 μg) from MGH mice was restricted with *Sst*I electrophoresed on a 1% agarose gel, transferred to nitrocellulose and hybridized with the nick-translated *Pst*I probe shown in Fig. 1*b*. pMGH (13 pg, left and 130 pg, right) was included as a hybridization standard. Markers are *Hin*dIII-cut λ DNA end-labelled with ^{32}P.

respectively. The RNA standard used contains about 10% GH mRNA on the basis of Rot analysis; therefore, we estimate that there are ~800–3,000 MGH mRNA molecules per liver cell in these transgenic mice (Table 1).

If all processing signals in the fusion gene are correctly recognized, a fusion mRNA 63 nucleotides larger than *bona fide* rat GH mRNA (~1 kb) would be generated[10,13]. Denaturing gel electrophoresis and RNA Northern blot analysis of the liver RNA from MGH-21 show that its size is similar, as expected, to that of authentic mouse and rat pituitary GH mRNA (Fig. 5*a*). Liver RNA from a control mouse shows no GH-reactive sequences (Fig. 5*a*, lane 1). Because the GH cDNA probe used for the RNA blot analysis recognizes both rat and mouse GH mRNAs, it is necessary to establish that the hybridizing species in the liver is actually the product of the fusion gene and not mouse GH mRNA due to an unexpected activation of the endogenous mouse GH gene. The use of a *Xho*I linker for the construction of the fusion gene generates a sequence that will be uniquely present in MGH mRNA. Thus, the *Xho*I site of pMGH was labelled using [γ-^{32}P]ATP and polynucleotide kinase, followed by cleavage with *Sst*I (Fig. 1*c*). This 221-nucleotide fragment was gel-purified, denatured, and used as hybridization probe in a single-strand-specific nuclease protection assay. Hybridization to MGH mRNA should generate a 74-base nuclease-resistant fragment while mouse GH mRNA or metallothionein mRNA will be unable to protect the kinased end and should therefore be negative. Figure 5*b*, lane 6 shows that the predicted 74-base fragment is present in liver RNA of mouse MGH-21, but not in normal mouse pituitary RNA (lane 5), control mouse liver RNA (lane 4) or in the liver RNA of MGH-3 (lane 3), an animal showing no accelerated growth (Fig. 3). Thus, it seems that transcription is initiating properly at the MT-I promoter and continuing through the putative termination site of the GH gene, the four GH intervening sequences are being properly spliced and the MGH mRNA is polyadenylated.

Increased growth hormone in sera of MGH mice

The correlation between MGH mRNA levels and growth of the mice sugggests that expression of the MGH gene accounts for the observed biological consequences; this was supported by the three independent RNA analyses above. These results suggest that the circulating levels of GH should be increased. Blood was taken from the transgenic mice and from littermates and assayed for GH by radioimmunoassay (RIA). The GH levels in four of the transgenic mice were 100–800 times greater than levels in control littermates; one mouse had 112 μg ml^{-1} of GH in its serum (Table 1). Two of the transgenic mice showing a slow but significantly elevated growth rate had serum GH levels at the high end of the normal range. The lack of physiological regulation and the ectopic production of GH in these animals probably account for their accelerated growth.

Discussion

These data strongly suggest that the altered phenotype of the mice is a direct result of the integration and expression of the metallothionein–growth hormone fusion gene. The elevated level of GH present in some of these mice corresponds to a high level of MGH mRNA in the liver (up to 3,000 molecules per cell). The accumulation of MGH mRNA in the liver is comparable to the endogenous level of MT-I mRNA[14], but is ~100-fold higher than that obtained from metallothionein–TK fusion genes studied previously[2]. This difference is probably the consequence of the intrinsic stability of the GH mRNA relative to TK mRNA; however, differences in transcription rates or processing efficiency due to variations in fusion gene construction are also possible. The high level of MGH gene expression in transgenic mice will greatly facilitate direct comparison of MGH and MT-I mRNA production in different tissues, thus allowing us to determine whether chromosomal location has an important effect on tissue-specific expression of the MT-I promoter.

Growth hormone levels in some of the transgenic mice were as much as 800-fold higher than in normal mice, resulting in animals nearly twice the weight of their unaffected littermates. This greater than normal accumulation of GH undoubtedly reflects both the lack of normal feedback mechanisms and expression of this gene in many large organs including liver, kidney and intestine. The effect of chronic exposure to high levels of GH is well documented[15], resulting in the clinical condition referred to as gigantism. This condition in humans is

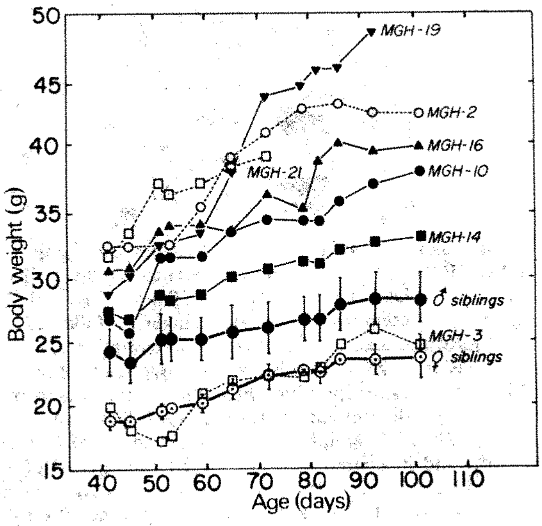

Fig. 3 Growth of MGH mice. Microinjected eggs (SJL×C57) were transferred to oviducts of foster mothers on 14 April; 21 animals were born 3 weeks later. At 33 days old they were weaned and the drinking water was supplemented with 76 mM $ZnSO_4$. The body weights of the males are shown as solid symbols; the mean weight (±s.d.) of 11 siblings not containing MGH sequences is also shown. The female weights are represented by open symbols; means (±s.d.) of three siblings are indicated also. MGH-21 died on day 72. A partial hepatectomy was performed on MGH-19 on day 56 and it was taken off Zn thereafter; it was killed on day 100. All mice were taken off Zn after day 83.

usually associated with pituitary adenomas[15] and more rarely with ectopic expression of GH by lung carcinomas[16,17].

Some of the diverse effects of GH are mediated directly by the hormone[18-20]. However, it is generally believed that the major effect of GH is stimulation of somatomedin production in the liver[18,19]. Somatomedins are insulin-like growth factors that promote proliferation of mesodermal tissues such as muscle, cartilage and bone[18,19]. The involvement of somatomedins in the GH response provides an explanation for the growth of animals such as MGH-10, 14 and 16 in which the circulating level of GH was only slightly higher than normal. In these animals, GH produced in the liver may be sufficient to stimulate somatomedin production because the local GH concentration is relatively high. Thus, in these animals, GH may mimic the local paracrine function of some hormones[21]. However, the reason for lack of growth of MGH-3 is unclear.

The implicit possibility is to use this technology to stimulate rapid growth of commercially valuable animals. Benefit would presumably accrue from a shorter production time and possibly from increased efficiency of food utilization. The effects of continuously elevated GH levels on the quality of meat will need to be evaluated. By choosing the appropriate GH gene, milk production may be disproportionately increased considering that GH is homologous to prolactin, that GH of some species binds to prolactin receptors, and that exogenously administered GH has been shown to increase milk yield[22,23]. Having a regulatable promoter may be particularly advantageous for timely expression of GH. Applying these techniques to large animals will be more difficult. Nevertheless, when genes for desired traits can be isolated, this approach should provide a valuable adjunct to traditional breeding methods. Optimizing the conditions for integration and expression of foreign genes in mice should facilitate the eventual application of these techniques to other animals.

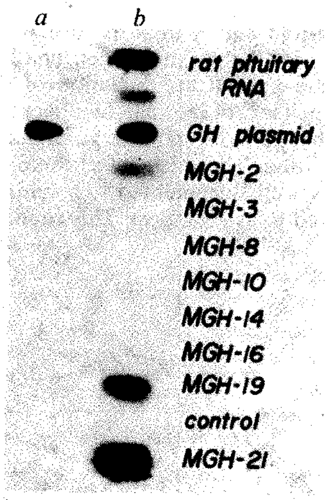

Fig. 4 Slot-blot analysis of liver RNAs from transgenic mice. Mouse liver RNA was purified by homogenizing a liver slice in 1×SET (1% SDS, 5 mM EDTA, 10 mM Tris *p*H 7.5), 200 μg ml^{-1} proteinase K (Boehringer) followed by phenol/chloroform extraction, ethanol precipitation, DNase I treatment (Worthington; DPFF), a second phenol/chloroform extraction, then re-precipitation with ethanol and finally resuspension for A_{260} determination. Liver RNA (30 μg) was diluted to 100 μl in 2X SSC. Samples were brought to 0.5 M NaOH or 0.5 M NaCl and incubated at 65 °C for 30 min. 140 μl of 20× SSC and 160 μl of 12.3 M formaldehyde were added, incubated at 65 °C for another 15 min and applied to a nitrocellulose sheet resoaked in 20× SSC through a slot-blot device[31]. The nitrocellulose was baked at 80 °C for 2 h, prehybridized for 5 h and then hybridized with nick-translated ^{32}P-rGH cDNA[32] (5× 10^6 c.p.m. in 4 ml at 42 °C overnight), washed in 0.1×SSC at 42 °C, and exposed to X-ray film at −70 °C for 24 h. *a*, Samples were treated with 0.5 M NaOH and neutralized with HCl. *b*, Samples were incubated with an equivalent amount of NaCl. 40 and 20 ng of rat pituitary poly(A)$^+$ RNA in the presence of 30 μg of control liver RNA were applied to slots as GH mRNA controls. 1 ng of rGH gene plasmid, also in the presence of 30 μg of control liver RNA, was applied as a base-resistant control.

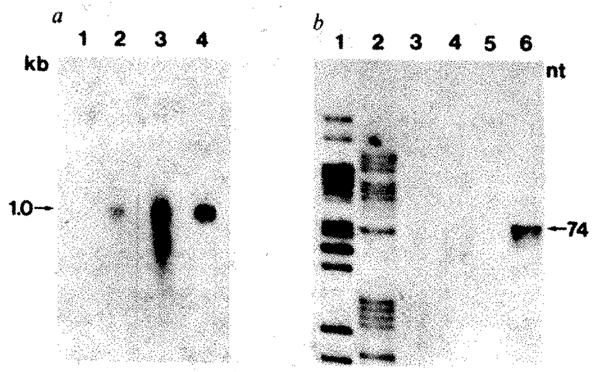

Fig. 5 Structure of MGH mRNAs in liver of transgenic mice. *a*, Northern blot analysis. RNAs were resuspended 10 mM NaH_2PO_4, *p*H 7.4/50% formamide/2.2 M formaldehyde, heated at 65 °C for 5 min, and subjected to electrophoresis on a slab gel composed of 1.5% agarose in 10 mM NaH_2PO_4, *p*H 7.4/0.55 mM EDTA/1.1 M formaldehyde. The running buffer was 10 mM NaH_2PO_4, *p*H 7.4/0.5 M formaldehyde. The gel was stained with acridine orange to identify rRNA markers, photographed, incubated for 90 min with 50 mM NaOH, and then neutralized with two washes of 0.2 M NaOAc, *p*H 4.3. The RNA was then transferred to diazotized paper and prehybridized as described elsewhere[32]. Lane 1, total liver RNA (15 μg) from a control littermate; lane 2, total liver RNA (15 μg) from MGH-21; 3, total mouse pituitary RNA; 4, 40 ng of rat pituitary mRNA, poly(A)$^+$. Lanes 1 and 2 exposed for 48 h; lanes 3 and 4 exposed for 5 h. *b*, Single-strand-specific nuclease protection assay. 20 μg of RNA were hybridized at 47 °C for 5 h in 40 μl of a solution containing 40 mM PIPES *p*H 6.4, 0.4 M NaCl, 80% formamide and 50,000 c.p.m. gel-purified 221-bp *Sst*I–*Xho*I fragment of pMGH end-labelled at the *Xho*I site with ^{32}P (see Fig. 1*c*). The samples were then diluted with 0.3 ml of 280 mM NaCl, 30 mM NaOAc *p*H 4.4, 4.5 mM $ZnSO_4$, 20 μg ml^{-1} salmon sperm DNA and 150 units of mung bean single-strand-specific nuclease (Collaborative Research) and incubated at 47 °C for 1 h. Samples were ethanol-precipitated, resuspended in 90% formamide containing bromophenol blue and Xylene Cyanol FF, loaded on to an 8% acrylamide–urea sequencing gel, electrophoresed for 1.5 h at 2,000 V, dried and autoradiographed for 7 days at −70 °C with an intensifying screen. Lanes 1 and 2, sequencing ladder used for size standards; 3, MGH-3 RNA; 4, control liver RNA; 5, mouse pituitary RNA; 6, MGH-21 RNA.

Another possibility is the use of this technology either to correct or to mimic certain genetic diseases. There are several inbred dwarf strains of mice, one of which, *little*, lacks GH and is about half normal size when homozygous[24]. Thus, introduction of the fusion gene described here or a natural GH gene might restore normal growth to these animals. On the other hand, the experiments described above show that gigantism can be created. Once these mice are inbred to give homozygous stocks, they will provide a valuable model system for biochemical studies on the consequences of excess GH production.

Finally, the exceptionally high levels of GH found in the sera of some of these mice raises the possibility of extending this technology to the production of other important polypeptides in farm animals. The concentrations of GH in MGH-21 serum was 10–100-fold higher than that reported for bacterial or mammalian cell cultures that were genetically engineered for GH production[10,25-27]. This genetic farming concept is comparable to the practice of raising valuable antisera in animals, except that a single injection of a gene into a fertilized egg would substitute for multiple somatic injections; moreover, the expression of that gene is likely to be heritable[9]. This approach may be particularly applicable in those cases where the protein of interest requires special covalent modifications (for example, proteolytic cleavage, glycosylation, or γ-carboxylation) for activity or stability.

Clearly the ability to introduce into mice, and by extrapolation into other animals, functional genes of selected construction offers wide ranging experimental as well as practical opportunities.

We thank Joan Vaughan for performing GH radioimmunoassays; Wylie Vale and Marcia Barinaga for valuable discussions; our colleagues for helpful comments; and Abby Dudley for secretarial assistance in the preparation of the manuscript. N.C.B. was supported by a NCI training grant (CA09370 HHS). The work was supported by research grants from the NIH (HD-09172, HD-15477, GM-26444, AM-21567) and NSF (PCM-8107172).

A millisecond pulsar

D. C. Backer*, Shrinivas R. Kulkarni*, Carl Heiles*, M. M. Davis† & W. M. Goss‡

The radio properties of 4C21.53 have been an enigma for many years. First, the object displays interplanetary scintillations (IPS) at 81 MHz, indicating structure smaller than 1 arc s, despite its low galactic latitude (−0.3°)[1]. IPS modulation is rare at low latitudes because of interstellar angular broadening. Second, the source has an extremely steep ($\sim\nu^{-2}$) spectrum at decametric wavelengths[2]. This combination of properties suggested that 4C21.53 was either an undetected pulsar or a member of some new class of objects. This puzzle may be resolved by the discovery and related observations of a fast pulsar, 1937+214, with a period of 1.558 ms in the constellation Vulpecula only a few degrees from the direction to the original pulsar, 1919+21. The existence of such a fast pulsar with no evidence either of a new formation event or of present energy losses raises new questions about the origin and evolution of pulsars.

A literature search in 1979 led to the suggestion that the steep-spectrum, IPS source was superposed on a flat-spectrum ($\nu^{-0.1}$) object with a diameter of ~60 arc s located to the west of the 4C position by one interferometer lobe (−31.6 s). Lobe identification errors in the 4C catalogue can occur in regions of confusion such as the galactic plane.

The superposition of two source components, one very compact with a steep spectrum and the other extended with a flat spectrum, was reminiscent of the radio properties of the Crab nebula and its pulsar in the pre-pulsar era[3]. The conjecture was made that the compact component in 4C21.53W was a pulsar as yet undetected due to pulse broadening of its radiation over one period by interstellar scattering. However, the IPS measurement placed an upper limit on interstellar scattering which, in turn, placed a limit on the pulse broadening. The conclusion was that only a very short period pulsar, $P \leq 10$ ms, would have been missed in metre wavelength searches owing to this effect. Searches for such a short period pulsar at centimetre wavelengths, where pulse broadening would be much reduced, were conducted at Arecibo Observatory and at Owens Valley Radio Observatory in 1979 without success.

After the 1979 pulsar searches, Erickson (personal communication) located a steep-spectrum compact source, 4C21.53E, east of the 4C position by one 4C interferometer lobe (+31.6 s). This observation provided evidence against the superposition hypothesis. Furthermore, Very Large Array (VLA) observations at 5 GHz by one of us (D.C.B.) showed that 4C21.53E was a compact double source with separation of 0.8 arc s.

Interest in the extended western object, 4C21.53W, returned when decametric observations at the Clark Lake Radio Observatory showed that both 4C21.53E and 4C21.53W had very steep spectra below 100 MHz (ref. 4). In addition, the Clark Lake observations indicated that the western source showed IPS at 34 MHz. The inferred brightness temperature exceeded $>10^{12}$ K.

Observations of 4C21.53W with the Westerbork Synthesis Radio Telescope (WSRT) at 609 MHz in January 1982

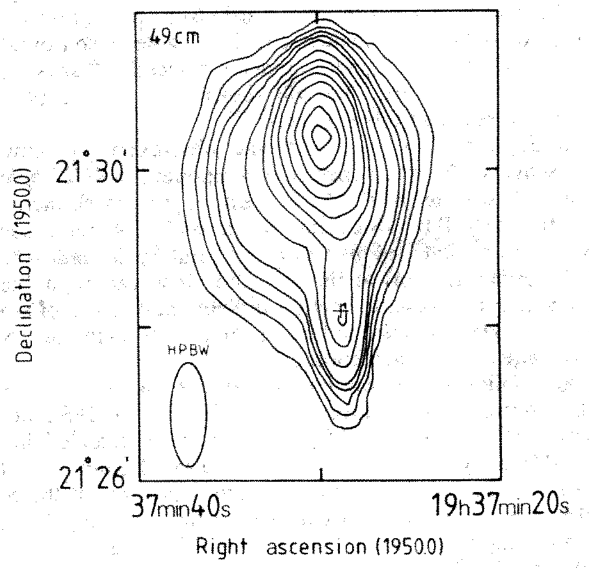

Fig. 1 Image of extended (north) and compact (south, +) components of 4C21.53W from a 12-h synthesis with the WSRT at 608.5 MHz on 15 January 1982. The synthesized beamwidth shown at the lower left is 31.3 × 80.4 arc s in RA and Dec, respectively.

* Estimated from compact source spectral index between 609 and 1,415 MHz.
† Corrected for beam sizes.

confirmed a suspected position discrepancy based on a Culgoora measurement at 80 MHz (ref. 5) and a Bonn measurement at 5,000 MHz (ref. 6) (Fig. 1). We suspected that the Culgoora position was dominated by the steep-spectrum component and that the Bonn position was dominated by the flat-spectrum, extended component. The division of 4C21.53W into two components, evident in Fig. 1, confirmed our suspicion. The southern and northern components were named 4C21.53W(com) or 1937+214 and 4C21.53W(ext) or 1937+215, respectively. A brief observation at the VLA confirmed the position and steep spectrum of 1937+214. A map of 4C21.53W at 1,415 MHz from a 12-h observation with the WSRT in August 1982 clearly resolved the compact and extended source component (Fig. 2). Recent WSRT observations and 1979 total power observations from Arecibo are summarised in Table 1. The spectra are decomposed into compact and extended object contributions. The Bonn measurement[6] is included for completeness. Erickson's decametric observations of this source are reported elsewhere[7].

The spectrum of the extended source is approximately that of an H II region, $\nu^{-0.1}$. The H 166α recombination line was detected at the Arecibo Observatory at the position of the extended source in November 1982. The line temperature is ~1% of the continuum temperature. The velocity of the line is $+2\ \mathrm{km\ s^{-1}}$ and its FWHM is $\sim 25\ \mathrm{km\ s^{-1}}$. These properties are comparable with those of an ordinary H II region. The small velocity does not distinguish between kinematic distances of 0 and 8.5 kpc.

The proximity of these two components of 4C21.53W on the sky suggests a possible physical connection. The morphology of the 21-cm continuum maps indicates that the exciting star may be displaced 43 arc s northwards from the centre of the H II region defined by the near-circular, low-level contours. On the other hand, the compact source is displaced 117 arc s southward from the centre. We will return later to the possible connection between these objects.

Interest in further pulsar searches was rekindled following the discovery of a steep-spectrum component in 4C21.53W at decametric wavelengths[4]. Momentum for the search increased when the 609-MHz WSRT map was available. A pulsar search sensitive to periods >4 ms was carried out by Boriakoss (personal communication) at the Arecibo Observatory in March 1982 without success. Detection in September 1982 of strong linear polarization at the compact source position in the WSRT maps made a pulsar detection a near certainty.

A new pulsar search was conducted with the 305-m antenna at the Arecibo Observatory on 25 September 1982 at the position of the compact 15 mJy component detected in the 1,400-MHz synthesis observations. Two harmonics of a millisecond periodicity, 1.558 ms, were discovered at the compact source position. The signal was present for only 3 min of a 7 min sample, and was not seen on a following day at either 1,400 or 2,380 MHz.

In November 1982 the pulsar search was intensified at Arecibo. In addition, we planned a search for interstellar scintillation (ISS) based on the possibility that the compact object was small, but not pulsing. Deep ISS modulation was detected at 1,400 MHz at the position of the compact source (Fig. 3). The amplitude was consistent with the flux density found in synthesis observations. The frequency and time correlation lengths, roughly 2 MHz and 5 min, respectively suggested a relatively small dispersion measure to the object, <100 electrons $\mathrm{pc\ cm^{-3}}$. This observation indicated immediately that the compact source 4C21.53W(com) or 1937+214, was extremely small as only pulsars have shown ISS previously. In addition, the modulation bandwidth and time scale were consistent with the single detection in September. On the following day the millisecond pulsar was confirmed.

The waveform of the pulsar contains a main pulse and an interpulse of comparable intensity separated by ~180° (Fig. 4). This morphology repeats precisely the main pulse/interpulse morphology of the Crab pulsar. The Crab pulsar has an additional 'precursor' component preceding its main pulse at metre wavelengths. The full widths at half intensity of the pulse components in Fig. 4 are <125 μs, or 8% of the period. The pulses are readily detected with the Arecibo telescope at 1,400 and 430 MHz with a fast signal averager and integrations of a few hundred pulses when positioned on a peak of the ISS modulation pattern (Fig. 3). The waveforms at both frequencies are similar.

The first observations have resulted in the following parameters: RA (1950.0) 19h 37 min 28.72 s, Dec (1950.0) 21° 28′ 01.3″, Barycentric period 0.001 557 807 (JD 244 5282), Dispersion measure 75 electrons $\mathrm{pc\ cm^{-3}}$. The accuracy of all values is a few parts in the last decimal place. The distance is estimated as 2,500 pc using an average n_e of $0.03\ \mathrm{cm^{-3}}$. There is no evidence for binary motion in timing measurements during the second week in November. Timing observations have been

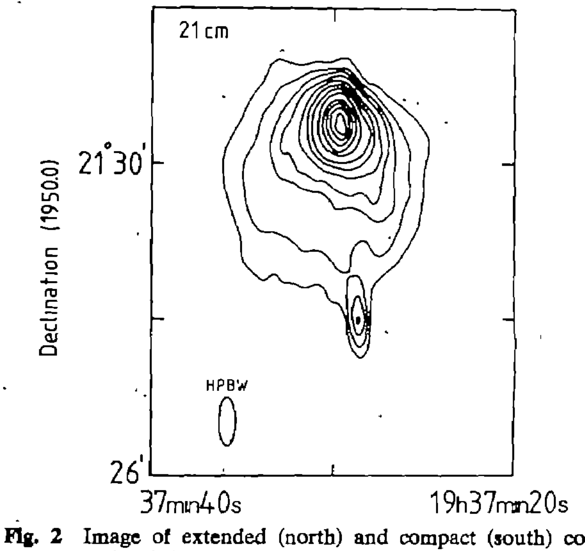

Fig. 2 Image of extended (north) and compact (south) components of 4C21.53W from a 12-h synthesis observation with the WSRT at 1,415 MHz on 8 August 1982. The synthesized beamwidth shown at the lower left is 13.3×37.0 in RA and Dec respectively.

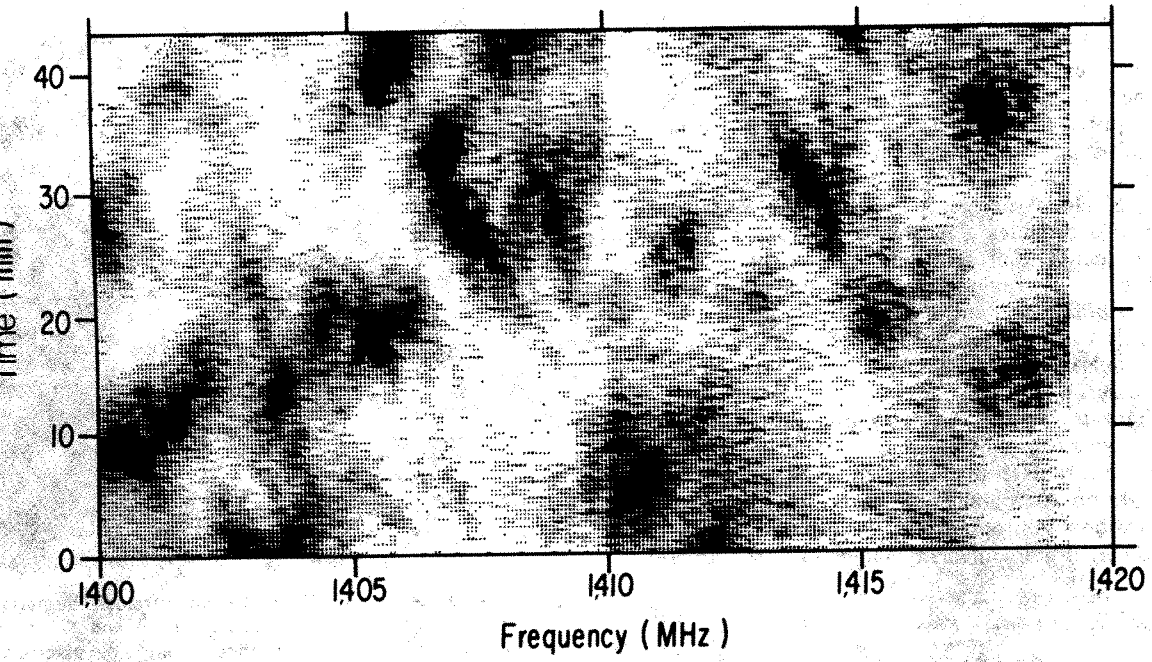

Fig. 3 Interstellar scintillation observation of compact component in 4C21.53W from Arecibo observations on 6 November 1982. Individual spectra were obtained for two polarizations in two 10-MHz bands every 30 s using a 252-channel, 1-bit autocorrelator. Spectra from the two polarization channels were summed and smoothed to a resolution of 100 kHz. The peak intensity in this dynamic spectrum is ~50 mJy.

initiated to determine the period derivative at the Arecibo Observatory. A previous estimate of the period derivative[8], based on a comparison of measured periods in September and November, has not been substantiated by timing data in November. We suspect that the September measurement was corrupted by sampling errors. Analysis of the November observations results in an upper limit to $\dot{P}$ of 10^{-15} s per s.

Our original hypothesis that 4C21.53W was a fast pulsar superposed on an extended synchrotron-emitting nebula was only half correct. Now we are faced with a more profound enigma: the existence of a pulsar rotating near the maximum rate possible for a neutron star with a surprising lack of evidence of energetic activity in the vicinity of the pulsar.

The present rotation rate, 642 Hz, is very near the maximum rate of 2,000 Hz where centrifugal forces balance gravitational forces at the surface of a 1 $M_\odot$ neutron star with 10 km radius. Matter on the equator would have a velocity of 0.13c. Changes in the equilibrium figure of the pulsar resulting from energy losses to magnetic dipole and gravitational quadrupole radiation (discussed below) may occur as abrupt starquakes if there is such a close balance between gravitational and centrifugal forces. The balance could be tipped in favour of gravity if the pulsar is denser than $\Omega^2/G \sim 2\times10^{14}$ g cm^3. The amplitude and frequency of starquakes, observable in pulse arrival time measurements, may be able to distinguish between standard (1 $M_\odot$) and high density models for the millisecond pulsar.

The present rotational energy content is 7×10^{51} erg for a neutron star moment of inertia 10^{45} g cm^2. This energy is comparable to the entire mechanical energy output of a supernova event. A higher density star, as suggested above, could reduce the present energy content if its moment of inertia were smaller than 10^{45} g cm^2. Both the rapid spin and the large energy content are indicative of a young object as energy losses to magnetic dipole and gravitational quadrupole radiation are strong functions of the rotation rate, Ω^4 and Ω^6, respectively[9]. The minimum energy loss for this pulsar will be the observed radio emission which amounts to 3×10^{30} erg s^{-1} assuming a beam solid angle of 1 sr.

The age of this pulsar is puzzling. The maximum spin rate for a neutron star is ~2,000 Hz. A model for the Crab pulsar by Ostriker and Gunn[9] predicts a period decay from this rate to 100 Hz in 1 yr due to gravitational quadrupole radiation. We do not observe such a rapid decay. Furthermore, there is a surprising absence of evidence of any debris from a recent neutron star formation event. Our radio maps show no synchrotron-emitting nebula in the vicinity of the pulsar. Einstein observations place a limit of 1.5×10^6 K for the surface temperature of a neutron star at the pulsar position for the indicated distance of 2 kpc, and exclude the possibility of a synchrotron nebula (D. J. Helfand, personal communication). These X-ray limits do not allow for possible heavy extinction. There is no source at the pulsar position in the COS B catalogue[10]. Lick Observatory observations reveal a 20 mag optical star at the position of the pulsar[11]. In direct analogy to the Crab pulsar, we expect this object will show optical pulsations.

We conclude that despite the large spin and rotational energy, this pulsar is not young. Evidently it has found a way to preserve a large fraction of its orignal energy. Minimal energy loss requires low values for the perpendicular magnetic dipole moment and the gravitational quadrupole moment. The first binary pulsar, 1913+16, is an example of a rapidly rotating neutron star (17 Hz) with a very low moments based on period derivative measurements. Observations of the spin decay will determine the dominant energy loss mechanism.

Two factors lead us to suggest that the pulsar and the H II region are related: (1) The two objects are in the same area of sky in a region of relatively low radio confusion. (2) The brighterst part of the H II region and the pulsar are displaced to opposite sides of the near circular, low-level contours of the H II region.

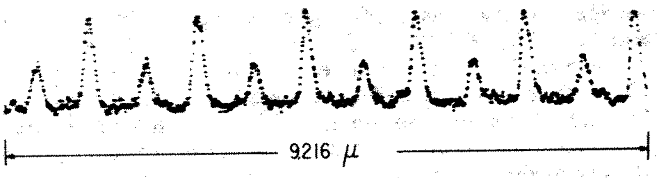

Fig. 4 Waveform of the millisecond pulsar from a signal averager oscilloscope display. Sample spacing is 9 μs. The full trace is roughly six periods, 9,216 μs. The integration lasted ~75 s. The waveform consists of a main pulse and an interpulse separated by nearly 180° of rotational phase. Errors in timing the signal averager and a 20 μs RC time constant are responsible for most of the pulse width.

We propose that the pulsar and the exciting star of the H II region were formerly members of a binary system. One of the components evolved and went through a quiet neutron-star formation stage. Formation of neutron stars in binary systems is also required to explain X-ray and radio pulsar binaries. A large and asymmetric energy and momentum transfer to the neutron star from the other component must have provided the escape velocity necessary to disrupt the binary orbit. This transfer also provides a means for creating a massive, high density object. The present separation of the pulsar from the centre for the H II region suggests an epoch for the disruption event of 7,800 yr ago and a distance of 2 kpc if we assume a typical pulsar transverse velocity of 150 km s^{-1}. Proper motion of the pulsar would be southward in declination of 0.015 arc s yr^{-1}.

We thank the staff of Arecibo Observatory for support and our colleagues for many exciting discussions. This research is supported by grants from the NSF and the Netherlands Foundation for Radio Astronomy. The Arecibo Observatory is part of the National Astronomy and Ionosphere Center which is operated by Cornell University under contract with NSF.

Optical identification of the millisecond pulsar 1937+214

S. Djorgovski

Astronomy Department, University of California at Berkeley,
Berkeley, California 94720, USA

Backer *et al.*[1] have reported the discovery of a pulsar with the period of 1.558 ms, identified with the source 1937+214 (=4C21.53). The extreme rotational velocity and high energy loss rate of this object make it a very interesting astrophysical phenomenum not only as an important clue for the physics of neutron stars and supernova remnants, but also as a potential strong emitter of gravitational radiation (S. White and J. Arons, personal communication). I present here an optical identification candidate for the millisecond pulsar: it is a 20th mag red object, undetectable on the Palomar Sky Survey prints. Finding charts and offsets from nearby stars are given.

The data were obtained on the night of 14 October 1982 UT, on the Lick Observatory 1-m telescope, in conditions of good seeing (FWHM ≅ 1 arc s). A red-sensitive TI 500×500 thin CCD was used as a detector, together with a sky-suppression red filter, purchased earlier by H. Spinrad. This wide red bandpass has an effective wavelength at about 6,500 Å and the width of ~1,400 Å. Three CCD exposures, one of 300 s and two of 600 s, were obtained. The frames were flatfielded with a 'dome flat', filtered to remove cosmic ray events, and had bad columns masked (standard CCD reduction procedure). The three frames were then offset into coincidence, and digitally stacked together, to increase the signal-to-noise ratio.

Part of the resulting image containing the object is shown in Fig. 1. Figure 2 shows a slightly larger region, enhanced by a new, highly nonlinear algorithm, which will be described elsewhere. The candidate object was found on all three CCD frames, although only the stack is shown here. Figure 3 shows a much larger field, as enlarged from a Palomar print.

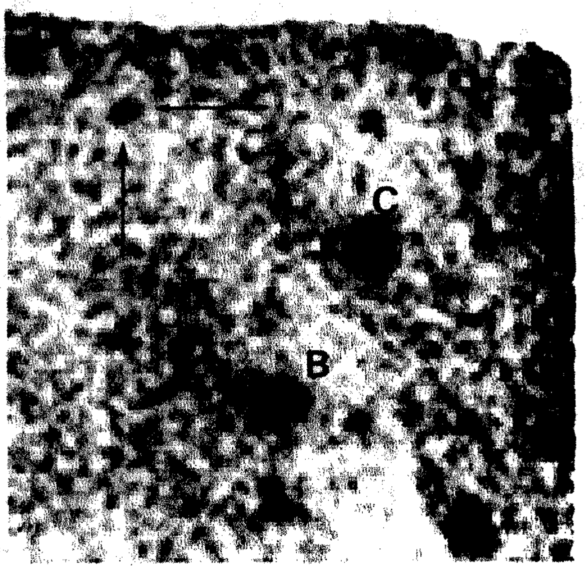

Fig. 1 A section of the CCD stack frame. The pulsar candidate is marked with the arrows. Stars B and C are those from Table 1. The field size is about 50 arc s, the pixel size 0.38 arc s. North is up, east to the left.

I have performed aperture photometry on the digital data of this source. In a pseudo-diaphragm of 6 arc s diameter, I obtain

$$m_r = 20 \pm 1$$

(the error may be an overestimate). The zero-point of the photometry was determined from a standard star, Feige 15, whose exposure was taken immediately after the pulsar field exposures. There is no extended emission associated with this source, down to the limit of these data.

I have also searched for the extended source (H II region ?), detected in radio observations, a few arc min to the north from the pulsar, and apparently associated with it. The result of this attempt was negative, but my data (one 600-s exposure) are of insufficient quality to place any interesting limits on the possible existence of extended optical structure there.

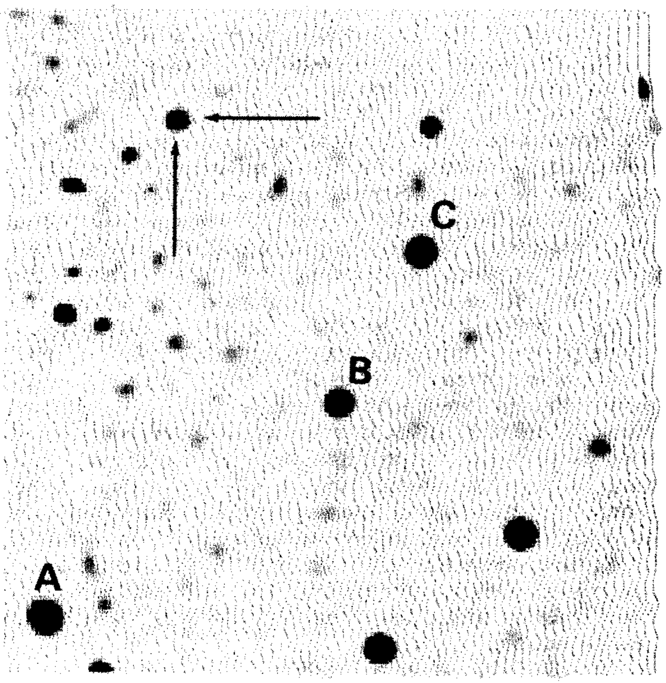

Fig. 2 Similar to Fig. 1, but strongly enhanced with a new, nonlinear technique. The field size is about 1 arc min. Faint 'objects' are not to be seriously believed.

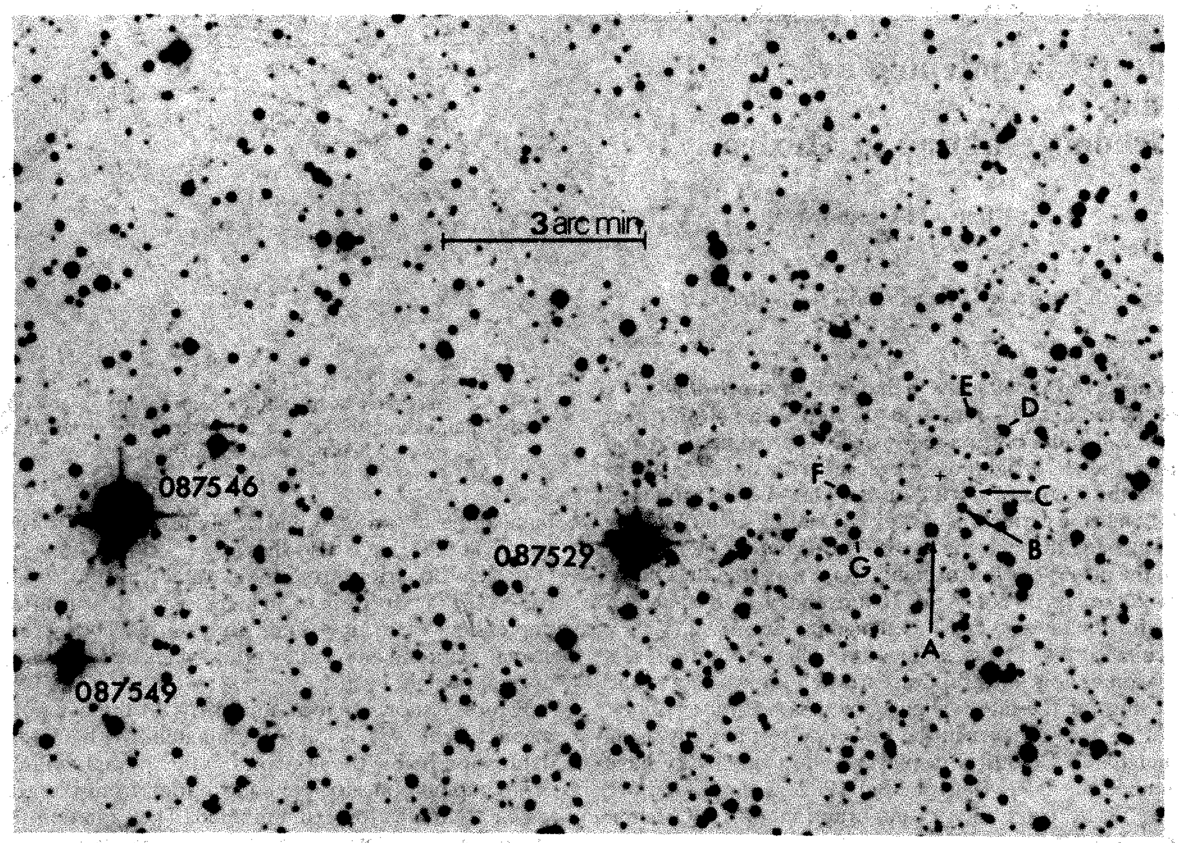

Fig. 3 Enlargement from the POSS chart E-185, showing the pulsar field, and stars denoted as in Table 1. Approximate pulsar position is marked with a cross. Horizontal bar gives the scale. North is up, east to the left. The whole Palomar chart shows high obscuration.

Table 1 lists several stars in this field, as marked in Fig. 3. Positions of the SAO stars were taken from the SAO catalogue. Stars A–G had their positions measured by J. Condon (personal communication), who quotes a random error of ~0.4 arc s. The radio position of the pulsar has been measured by Backer at the Very Large Array.

Pixel coordinates on the CCD stack frame were measured for stars A, B and C, as well as the pulsar candidate, and the faint object south-east from it. The relation between these (CCD) and equatorial coordinates was found, and the position of the optical pulsar candidate was derived from it. I have obtained the following differences:

$$\Delta\alpha \text{ (Condon/radio} - \text{Djorgovski)} = -1.65 \pm \sigma \text{ arc s}$$

$$\Delta\delta \text{ (Condon/radio} - \text{Djorgovski)} = +1.52 \pm \sigma \text{ arc s}$$

where $\sigma \geq 1$ arc s. This error includes Condon's quoted error of 0.4 arc s, and the estimated error of my measurements, which is at least 0.6 arc s. There is also an unknown contribution from distortions of the CCD field (which may add as much as 0.1–0.5 arc s to this error). I believe that the realistic error bar is more like 1.5 arc s. Thus, my optical candidate is within about 1σ error box from the radio position. There is a slight possibility that the very faint object south-east from the candidate star is the correct identification; however, this object may also be spurious (a CCD artefact).

Table 1 Positions and offsets for the stars in the field

Star	α (1950.0)	δ (1950.0)	Star–Pulsar Δα (arc s)	Δδ (arc s)
PSR1937 + 215	19 h 37 min 28.72 s	+21° 28′ 01.3″	0	0
SAO-087529	19 h 37 min 48.85 s	+21° 27′ 06.5″	281.0	−54.8
SAO-087546	19 h 38 min 22.48 s	+21° 27′ 32.9″	750.5	−28.4
SAO-087549	19 h 38 min 25.92 s	+21° 25′ 24.2″	798.7	−157.1
Condon A	19 h 37 min 29.66 s	+21° 27′ 16.9″	13.1	−44.4
Condon B	19 h 37 min 27.69 s	+21° 27′ 36.8″	−14.4	−24.5
Condon C	19 h 37 min 27.12 s	+21° 27′ 50.8″	−22.3	−10.5
Condon D	19 h 37 min 24.90 s	+21° 28′ 45.1″	−53.3	43.8
Condon E	19 h 37 min 27.01 s	+21° 29′ 01.5″	−23.9	60.2
Condon F	19 h 37 min 35.30 s	+21° 27′ 51.3″	91.9	−10.0
Condon G	19 h 37 min 34.60 s	+21° 27′ 14.4″	82.1	−46.9

Further photometry (and, in particular, search for variability) and spectroscopy are needed. A search for optical pulses from this object has been initiated by D. Cudaback and J. Middleditch (personal communication).

Backer *et al.*[1] have determined the dispersion measure towards this source, and from it an estimate for the distance to it, ~2.4 kpc. It has been proposed independently by D. Van Buren (personal communication) that this source may be associated with the Vulpecula OB association, about a degree to the west. The distance to this association is estimated to be ~2 kpc.

This object has almost the same brightness in the present CCD red bandpass, as the faint star just north from the star C, and which is easily detectable on the Palomar red print. However, the object is invisible on the same print. The two bandpasses (CCD and POSS) are not very different, so that colour effects can hardly explain this discrepancy. It is then possible that this object had increased in apparent brightness at least a magnitude over the past couple of decades.

We thank Don Backer for ideas and stimulation, Vicki Lindsay for help in obtaining the data, and many colleagues in Berkeley for stimulating discussions. Lick CCD data taking system and flat fielding program were written by T. Laver and R. Stover. This work was partly supported through a University of California graduate fellowship.

Twilight IR brightening over India due to El Chichón's eruption in Mexico

N. M. Ashok, H. C. Bhatt, T. Chandrasekhar & J. N. Desai

Physical Research Laboratory, Ahmedabad-380009, India

We have observed an unusual behaviour in the twilight sky brightness in the near IR region associated with volcanic dust from the El Chichón eruption in Mexico. Approximately 8 min after sunset the sky brightness increases with time for about 8–10 min in the I band ($\lambda_{\rm eff} = 0.87$ μm). This may be explained by a variation in the extinction of the illuminating solar radiation during its passage through the aerosol layer before being scattered into the observer's line of sight. Here, we estimate a mean height of 22 km, a thickness of 10 km and a drift speed of 19 km h^{-1} for the layer over Ahmedabad in June 1982.

Spectacular visual effects in the form of coloured sunsets following violent volcanic eruptions are well known[1,2], and the time of fading for the late twilight glow has been interpreted in terms of an aerosol layer in the lower stratosphere by using shadow heights[3,4]. Colourful displays in the twilight sky have occurred since the latter half of May 1982 in India, and are thought to result from the recent eruption of El Chichón Volcano[5] in Mexico.

Observations were carried out at Thaltej (23°03′ N, 72°30′ E) near Ahmedabad using a solid state photometer in the I band ($\lambda_{\rm eff} = 0.87$ μm; $\Delta\lambda_{\rm eff} = 0.25$ μm) coupled to a Celestron-14 telescope. At this wavelength (located between two water vapour absorption bands), the troposphere is expected to be more transparent than the volcanic dust-laden lower stratosphere. This wavelength band is therefore ideal for detecting stratospheric dust. Figure 1 shows the time variations of the I band intensity on 8, 9 and 15 June 1982. A normal twilight curve[6] at 0.75 μm is also shown.

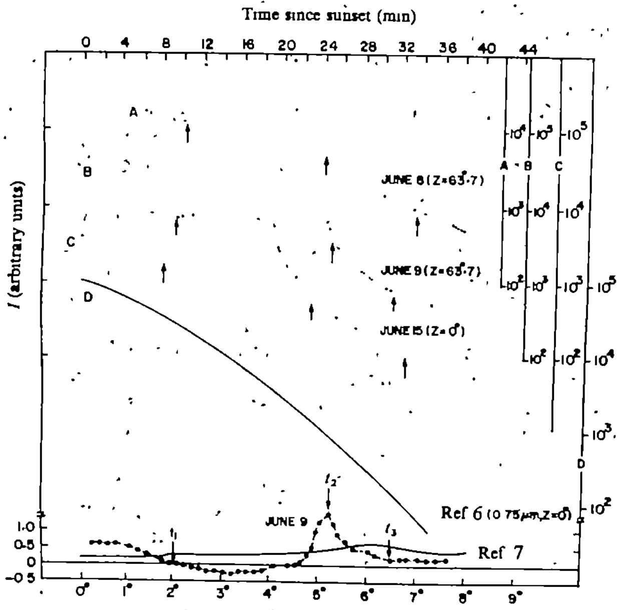

Fig. 1 Light curves A, B, C show the I band intensity (I) variation with time after sunset. D refers to the normal twilight curve at 0.75 μm (ref. 6). The plot at the bottom shows $-d/d\alpha \log I$ as a function of time after sunset for the light curve B corresponding to 9 June 1982. Also shown is the derivative curve for normal twilight at 0.659 μm (ref. 7). Times t_1, t_2 and t_3 decribed in the text have been indicated by means of arrows.

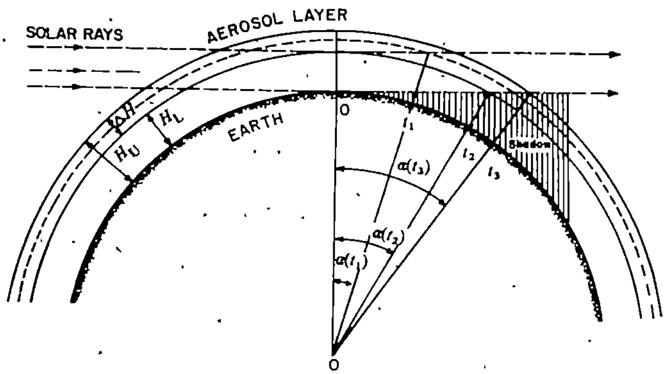

Fig. 2 Geometry of the situation for zenith observations. Solar rays illuminating the aerosol scatterers suffer attenuation during their paassage through the layer.

A clear departure from the normal twilight drop in intensity can be seen in the form of an increase in intensity after a shallow depression occurring ~8 min after sunset. The increase culminates in a broad maximum after which it falls sharply to the normal twilight level.

Figure 2 shows that at sunset ($t = 0$) the aerosol layer at a mean height ($\bar{H}$) is fully illuminated. With increasing solar depression below the horizon (α) the normal twilight intensity drops rapidly, but not the contribution from the aerosol layer which continues to be illuminated. The radiation illuminating the aerosol scatterers suffers increasing extinction with time due to its increasingly long passage through the layer. At time t_1 the central light ray has the longest passage through the layer and the extinction is at a maximum, thereby giving rise to a minimum in the observed intensity.

Due to the curvature of the Earth and the finite thickness of the layer, the total light path through the layer and the extinction are reduced after time t_1. The observed intensity consequently increases, reaches a plateau and then falls gradually due to the increasing attenuation of light reaching the aerosol scatterers by the lower atmosphere. At time t_2 the shadow of the Earth begins cutting off the illumination to the layer from the lower end. At time t_3, the shadow has completely cut off the layer and the intensity drops to the normal twilight level.

A model considering extinction of solar rays in the aerosol layer based on the above geometry has been evolved to explain the observed features. A uniform layer with a thickness of ΔH is considered. The extinction ($A_{\rm I}$) suffered by the light reaching the aerosol is calculated using the relation

$$A_{\rm I}(x,t)=\begin{cases} k_{\rm I}R\left\{\left[\sin^2\alpha(t)+\dfrac{2\Delta H}{R}\left(1-\dfrac{x}{\Delta H}\right)\right]^{1/2} \right. \\ \left. -2\left[\sin^2\alpha(t)-2\dfrac{\Delta H}{R}\left(\dfrac{x}{\Delta H}\right)\right]^{1/2}+\sin\alpha(t)\right\} \\ \quad \text{for } \alpha(t)>\sin^{-1}\left(\dfrac{2x}{R}\right)^{1/2} \\ k_{\rm I}R\left\{\left[\sin^2\alpha(t)+2\dfrac{\Delta H}{R}\left(1-\dfrac{x}{\Delta H}\right)\right]^{1/2}+\sin\alpha(t)\right\} \\ \quad \text{for } \alpha(t)\leqslant\sin^{-1}2x/R\left(\dfrac{2x}{R}\right)^{1/2} \end{cases}$$

where $A_{\rm I}(x,t)$ is the extinction suffered by the I band intensity reaching the observer at time t after scattering by an aerosol particle located at a distance x above the lower height ($H_{\rm L}$) of the layer. $k_{\rm I}$ is the extinction per unit length in the I band, $\alpha(t)$, the solar depression angle at time t, ΔH, the layer thickness and R, the radius of the Earth.

0028–0836/82/500620—02$01.00

The model I band intensity at time t is then given by

$$I(t) \propto \int_0^{\Delta H} \exp(-A_I(x,t))\,dx$$

This line of sight integration has been numerically evaluated for various values of k_I and ΔH. Figure 3 shows the result for $\Delta H = 10$ km and $k_I = 3\times10^{-8}$ mag cm^{-1}. The calculated intensity passes through a clear minimum (corresponding to t_1) and then increases to reach a plateau. Despite uncertainties introduced by the unknown normal twilight intensity on which the dust contribution is superimposed, the agreement between the model and the observations in explaining the unusual brightening appears satisfactory.

The times t_1, t_2 and t_3 used in the calculation of layer height and thickness are listed in Table 1. The times have been obtained from $-d \log I/d\alpha$ against t plots. The lower end of Fig. 1 shows a representative plot of this derivative curve for 9 June. A derivative curve for the normal twilight obtained at 0.659 μm is also shown for comparison.

Table 1 Calculation of height and thickness of aerosol layer

Date	t_1		t_2		t_3		ΔH (km)	H_L (km)	H_U (km)
	min	s	min	s	min	s			
8 June 1982	10	20	24	12	33	22	9.4	16.5	31.8
9 June 1982	9	24	25	0	31	12	8 0	17.6	27.5
15 June 1982	8	12	23	0	32	24	9.2	17.0	36.1

The lower height of the aerosol layer (H_L) has been evaluated from time t_2 using the expression[8]:

$$H_L = R\{1-\cos\alpha(t_2)\}\frac{\cos Z}{\cos\psi},$$

where $\alpha(t_2)$ is the solar depression angle at t_2 corrected for refraction due to a double passage through the atmosphere, Z is the zenith angle of the observation and $\psi = Z - \alpha(t_2)$. An upper limit to the height (H_U) is determined in a similar way using t_3. The time t_1 is used in evaluating layer thickness (ΔH) from the relation (valid for zenith)

$$1 - \Delta H/2R \simeq \cos\alpha(t_1) \text{ or}$$

$$\Delta H \simeq R\alpha^2(t_1)$$

For zenith angles departing from zero appropriate corrections to t_1 and hence $\alpha(t_1)$ have to be made before evaluating ΔH.

The analysis yields a mean lower height of the aerosol layer $\bar{H}_L = 17.0 \pm 0.6$ km, an upper limit to the height of the layer $\bar{H}_U = 32 \pm 4$ km, and layer thickness $\overline{\Delta H} \simeq 9$ km. Note that the normal summer tropopause height at 23° latitude is ~17 km. The observations show the unusual brightening in I (0.87 μm) and R (0.66 μm) but only an inflection in the V(0.54 μm) light curve. A spectral index $\beta(I_{scatt} \propto 1/\lambda^{\beta})$ evaluated from the observations and corrected for reddening due to the lower atmosphere yields a value of 3.7 at 15 min before sunset, 1.3 at the time of the peak I band intensity and 3.4 after the passage of shadow through the layer. The low value of β at the time of the peak I band intensity indicates that the radiation received at that time comes predominantly from scattering by the aerosol layer.

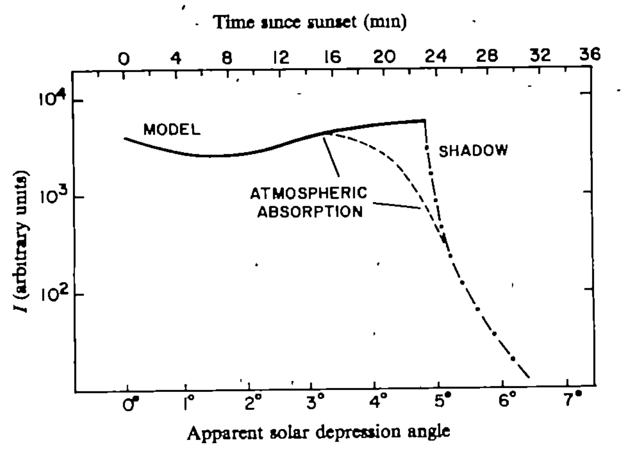

Fig. 3 A light curve computed from the aerosol layer model ($\bar{H} = 22$ km, $\Delta H = 10$ km, $k_I = 3\times10^{-8}$ mag cm^{-1}). The effects of the atmospheric absorption (-----) and the Earth's shadow (—·—·) are shown.

A lower limit to the mass of the aerosol layer M_d can be estimated by using extinction A_I calculated by comparing the peak intensity to the intensity at time t_1. A lower limit to the value of extinction at the time of the maximum length light passage through the layer (~500 km for $\bar{H}$ ~ 22 km) is given by $A_I > 0.763$ mag. This yields

$$M_d > 3.68\times10^{12}(f/Q)\left(\frac{a}{0.15\ \mu\text{m}}\right)\left(\frac{\rho_g}{1\text{ g cm}^{-3}}\right)A_I\,g$$

where a is the aerosol particle size in micrometres, ρ_g the grain density in g cm^{-3}, Q the dimensionless extinction efficiency factor and f the fractional area of the Earth covered by the layer. For a latitude spread of the layer of ±20° f ~ 0.3. Taking a ~ 0.15 μm, ρ_g ~ 2, Q ~ 0.5 we get $M_d \gtrsim 4\times10^6$ tonnes. The earliest positive sighting of volcanic layer features occurred in Ahmedabad about 40 days after the El Chichón eruption, implying drift speed of ~19 km h^{-1} from this delay.

Anti-phase domain boundary tubes in Ni_3Al

C. T. Chou & P. B. Hirsch

Department of Metallurgy and Science of Materials,
University of Oxford, Parks Road, Oxford OX1 3PH, UK

M. McLean & E. Hondros

National Physical Laboratory, Teddington,
Middlesex TW11 0LW, UK

The mechanical behaviour of ordered alloys has caused much scientific and engineering interest[1,2]. The engineering interest is due to the fact that many ordered compounds, which have unusually good mechanical properties, are incorporated as dispersed particles in and contribute to the high strengths of some high performance commercial alloys (for example, Ni-base superalloys and certain Al alloys). The scientific emphasis has been directed towards understanding the physical basis of the high strengths of these materials and anomalous behaviour such as the increase in yield strength with temperature. We report here preliminary results based on transmission electron microscopy (TEM) studies of the defect structures in the compound Ni_3Al which is the principal strengthening constituent of nickel-base superalloys used in gas-turbine engines: our observations confirm the existence of a new type of defect, anti-phase domain boundary tubes (APB) which we suspect may be an important contributor to the high strengths of these compounds.

In many nickel-based alloys the high-temperature strength is provided by the γ' precipitate based on Ni_3Al, an ordered phase with the $L1_2$ structure. The flow stress of the γ' phase reaches a peak value at about 700 °C. Several theories have been put forward to explain this anomalous behaviour[3] with

0028-0836/82/500621—03$01.00

associated TEM studies[4,5] to characterize the dislocation configurations, but these have not succeeded in explaining all features of this behaviour. Recently, the existence of APB tubes in an Fe–Al alloy with B2 ordered structure has been demonstrated[6,7]. The existence of these tubes had been previously predicted[8] and they have been invoked to explain the high work hardening rates of ordered alloys by providing additional drag forces on jogged dislocations[9,10]. In principle, APB tubes should occur during the deformation of a wide variety of ordered alloys. We therefore expect that the investigation of APB tubes in the γ' phase might provide a better understanding of the unusual deformation behaviour of this phase and give some insight into the strengthening mechanisms of Ni-base superalloys.

The early stages of this work have been carried out on polycrystalline specimens of Ni_3Al with columnar grains along the ingot axes. Ingots were prepared by melting the constituent elements and casting into 12.5 mm diameter copper moulds in a vacuum of $\sim 3\times10^{-5}$ torr. The ingots were remelted and directionally solidified in argon atmosphere at 10 mm h^{-1} in a temperature gradient of 15 K mm^{-1} followed by homogenization at 1,200 °C for 48 h.

The ingots were spark cut into rods with diameters ~3 mm and lengths ~6 mm. The rods had the columnar grains oriented along their axes. These specimens were compressed 3–5% at one of the following temperatures: room temperature, 200 and 400 °C. Thin foils for TEM work were prepared from slices of the deformed rods; the final electropolish was carried out in a solution of 5% perchloric acid in ethyl alcohol at −50 °C and 15 V. The foils were examined in a JEOL JEM 100B microscope fitted with a top entry stage which allows ±30° of tilt. The 'weak beam' technique with superlattice and fundamental reflections was used.

The following results were obtained from a specimen with surface close to the (112) plane. The sample was compressed at 400 °C to $\delta = 4.1\%$. Figure 1 shows weak beam images of the same area using three non-coplanar fundamental reflections. Contrast experiments have proved that the stacking faults in these pictures are $\langle 112\rangle$ type. Figure 2A shows dotted lines parallel to [011] or [101] in this area in a semi-weak beam image when the superlattice reflection $02\bar{1}$ was used; the deviation parameter w was ~21 (~2 g was satisfied). These features are not apparent in the fundamental reflection modes (Fig. 1). Figure 2B is a superlattice reflection weak beam image of the same area. The reflection used was $20\bar{1}$. The deviation parameter here is $w\sim42$ (~3g was satisfied).

The lines in Fig. 2B are longer than the corresponding lines in Fig. 2A due to different tilts of the specimen. From the position of Kikuchi lines relative to the diffraction spots, it was possible to determine (1) the sense of the tilting and (2) from the observed length changes, that these lines are along (011) and not [101].

The contrast shown by the lines can be summarized as follows: (1) The defects are along $\langle 011\rangle$, the Burgers vector direction in the material. (2) the defects are visible only when superlattice reflections are excited. (3) The oscillatory contrast in Fig. 2A and B shows that the defects are line defects. (4) The fringes are symmetrical about the centre of the specimen and no fringes occur when $w=0$; this latter effect is characteristic of the contrast from two overlapping APBs[6]. (5) The width of these defects does not change with deviation parameter.

All of these characteristics are as expected for APB tubes. It can be established unambiguously that these defects are not dislocations as they are invisible in any of the three non-coplanar fundamental reflection pictures (Fig. 1) which should image all possible dislocations. Again, the features can not be Lomer–Cottrell (LC) locks since although in f.c.c. structures these are along $\langle 011\rangle$ directions (those with $\mathbf{b}=a/2\,[01\bar{1}]$ are along [011]) they should be visible in Fig. 1A and C, since in these cases the invisibility criterion $\mathbf{g}\cdot\mathbf{b}=0$ does not hold. In fact LC locks are edge dislocations and they should also be visible in Fig. 1B, because the $\mathbf{g}\cdot\mathbf{b}\times\mathbf{u}=0$ criterion does not hold, even though $\mathbf{g}\cdot\mathbf{b}=0$ in that case. Neither can the defects be normal anti-phase domain boundaries. If they were two

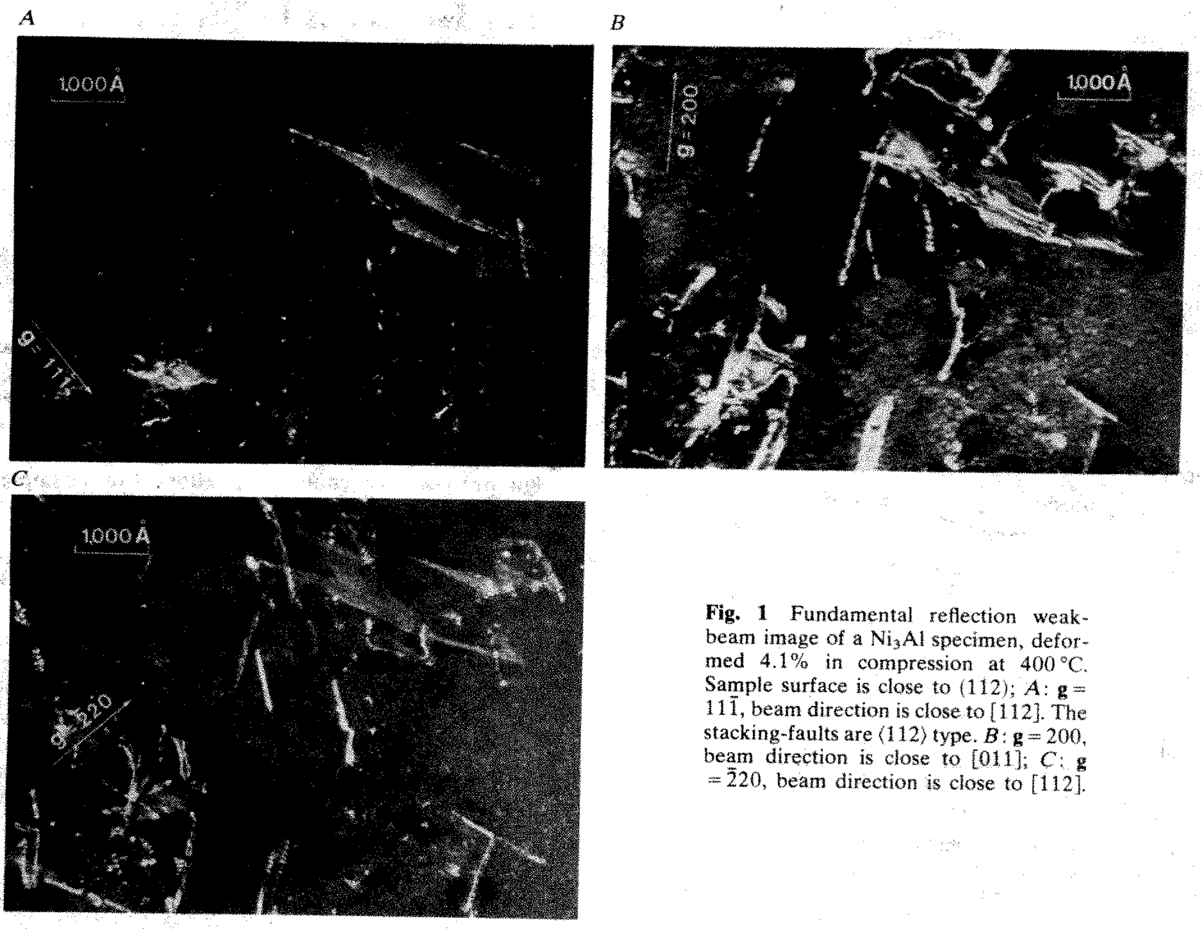

Fig. 1 Fundamental reflection weak-beam image of a Ni_3Al specimen, deformed 4.1% in compression at 400 °C. Sample surface is close to (112); A: $\mathbf{g}=11\bar{1}$, beam direction is close to [112]. The stacking-faults are $\langle 112\rangle$ type. B: $\mathbf{g}=200$, beam direction is close to [011]; C: $\mathbf{g}=\bar{2}20$, beam direction is close to [112].

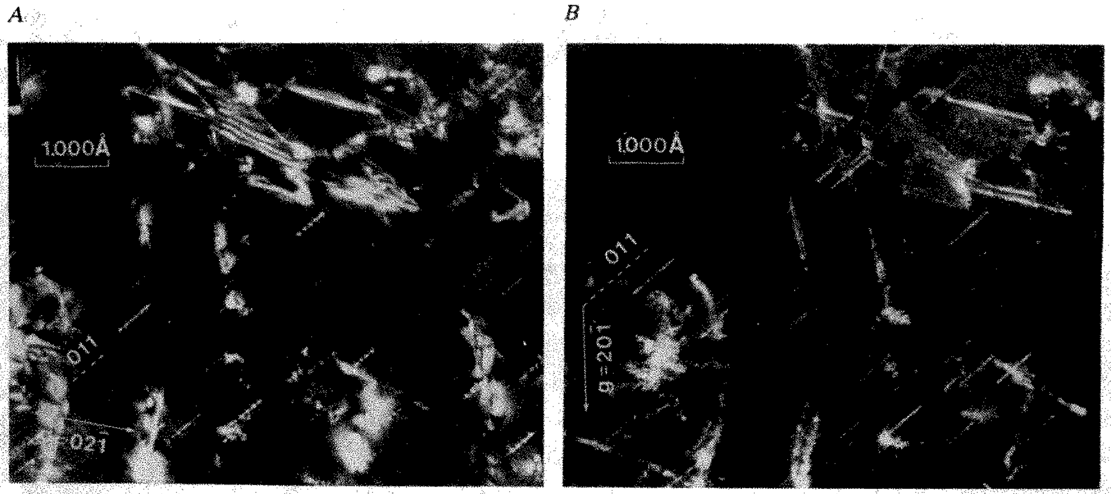

Fig. 2 Superlattice reflection weak-beam image of the same area as that in Fig. 1*A*: $\mathbf{g}=02\bar{1}$, $w \simeq 21$; beam direction is close to [548]. *B*: $\mathbf{g}=20\bar{1}$, $w \simeq 42$, beam direction is close to [326].

dimensional APBs they should not show depth oscillations as in Fig. 2. If they were narrow strips of APBs, they should be connected to partial dislocations, but the latter are strongly imaged using the fundamental reflections. The above discussion leads to the conclusion that the defects along [011] in Fig. 2 are APB tubes.

APB tubes have now been found in deformed ordered alloys with B2 (refs 6, 7) and $L1_2$ superlattices, suggesting that they may be a general feature in deformed ordered alloys. On the other hand their importance in affecting mechanical properties remains to be assessed. Experiments are under way to determine *inter alia* whether the peak in the curve of flow stress as a function of temperature may be associated with the temperature at which climb helps jogs in edge dislocation to align, and in screw dislocations to move non-conservatively, and how APB tubes play a role in superalloys with large proportions of γ' phase.

We thank Miss P. Henderson for providing material, and Dr P. Pirouz for help with the deformation of the specimens; C.T.C. thanks the National Physical Laboratory for financial support.

A lightning-associated phenomenon and related geomagnetic measurements

P. W. Burbidge & D. J. Robertson

Department of Physics, University of Auckland, Private Bag,
Auckland, New Zealand

Many observations of phenomena associated with lightning have been made at a considerable distance. Apart from the element of personal danger from direct strike, wind and rain make field conditions unfavourable for observing, and the phenomena are usually very transient. We report here a phenomenon associated with lightning which was observed indoors and at close range following a lightning strike. Magnetic field measurements in the room where the phenomenon was seen are also reported.

In the late evening of 8 September 1981 a thunderstorm approached Te Ngaere (35° 01′ 24″S, 173° 52′ 10″E), 300 km north of Auckland, New Zealand. The one-storey house at Te Ngaere, where the observation was made by Mrs E. V. Sale, is one of a row built behind a sandy beach and occupies the highest point of a low sand-bar at the mouth of a swampy valley. The house is constructed of timber with a cement-tiled roof and steel-reinforced concrete floor. The living-room has a partition (behind the piano in Fig. 1) forming an entry way about 2 m wide. There is a French door with a corded woollen mat just inside. The floor is covered with felt-lined linoleum. Mrs Sale had brought in some wet steel tools, which she had roughly dried and laid out to dry fully on a doubled sheet of newspaper 60 cm by 40 cm (Fig. 1). She was kneeling at the east side of the paper bending over the tools when another heavy lightning strike occurred, just outside the house. Mrs Sale is an amateur astronomer and impressed us as a reliable observer. She related the events as follows:

> The next lightning seemed directly overhead and very bright and was accompanied by a simultaneous very loud clap of thunder. I looked up as the whole house shook and then looked down and saw a flow of light come in under the door. It settled in a blob near the edge of the area where the tools were laid out. It was not in any true shape but about 3 or 4 inches long and 2 inches wide, moving along the floor, less than half an inch thick, seemingly fluid in shape and texture. It reminded me of quicksilver, being a bluish-silver colour and it had rounded sides like a blob of mercury. It was brighter at the edges than in the middle, but it did not seem, especially in the light of the room, to glow, nor did it give out sparks.
>
> From the central body arms flowed out like runs of oil among the tools. The trails weaved through the tools—not actually over them but round them—moving back into the main body of the blob and then going out doing the same kind of movement over again. There was no sound or smell. The arms finally all went back into the blob which disappeared again suddenly out under the door. There was no bang and when I ventured to touch the tools there was no charge on them.

We visited the house on 16–18 November 1981. From this visit together with subsequent correspondence, a more detailed account can be given.

0028–0836/82/500623—02$01.00

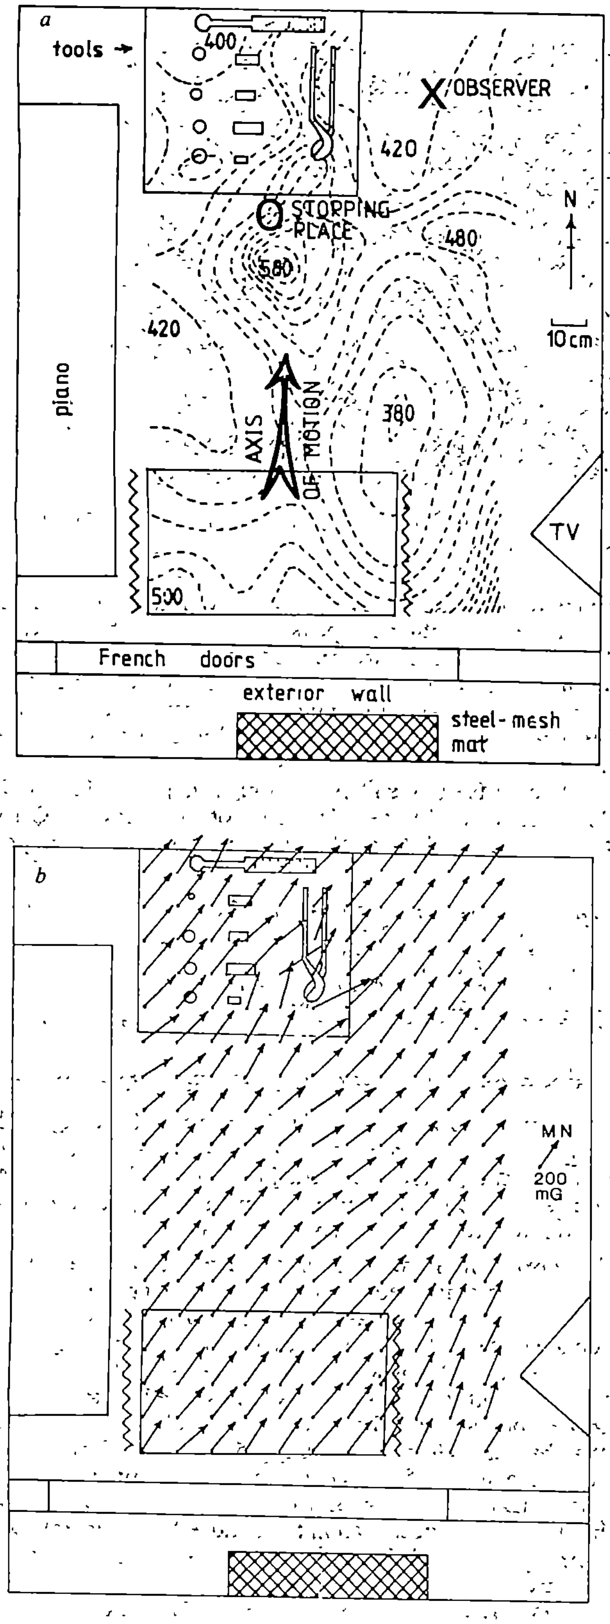

Fig. 1 *a*, Sketch of the region in which the body was observed, showing the observer's position and the path of the body. The vertical magnetic field intensity in milligauss is superimposed, with a contour interval of 20 mG. *b*, Horizontal component of magnetic field, over the same area. Intensity scale is given on the right.

The body was opaque, and must have looked like a faintly luminous blob of milky glass. No trace of it was left anywhere. A strike point could not be found for the lightning and there was no sign of damage to the exterior television antenna, vertically above the set in Fig. 1, or to a large pohutukawa tree a few metres south-east of it. The door was found to have a tapering vertical gap near the bottom, close to the floor about 10 cm long and 0.5 cm wide.

The lighting in the area of the living-room was dim and indirect, coming mainly from a shaded 60 W standard lamp about 4 m away. In an experiment Mrs Sale felt that a blob of freshly poured lead replicated the luminosity of the object when it was illuminated by a candle 10 cm away. We estimate the power emitted as light therefore as $\sim 2\times10^{-4}$ W; no noticeable heat was emitted. Two timing measurements were done as Mrs Sale rehearsed the motion of the body by pointing. The two agreed, giving 4 s for each travel and 7 s halt, a total of 15 s.

As the phenomenon occurred during a thunderstorm and immediately after a heavy strike of lightning in the vicinity, it may be related to that broad group of events currently classified as "ball lightning"[1–3].

Magnetic fields in the vicinity were measured with the tools in place on 17 November 1981. This may be of particular interest as although many accounts of ball lightning refer to iron objects such as axes, stoves and tramlines only one previous author[4] has explored magnetic effects. The geomagnetic field at floor level was mapped near the path of the body with a laboratory fluxgate magnetometer (Schoenstedt DM-2220). Three-axis measurements were facilitated by setting the unidirectional probe in a wooden cube with 6.3-cm sides and taking readings with successive orthogonal faces of the cube resting on the floor and squared against a wooden rule. Each of the observed elements varies over the floor by ~20% which is not unusual for steel-reinforced concrete.

The ambient geomagnetic field is steeply dipping at about 60° above horizontal, and the body was evidently constrained to move in the horizontal plane. If the body contained free dipoles such as current loops, then after alignment by the field it would be expected to experience a force towards the region of most intense vertical field, and possibly move in that direction. It will be seen in Fig. 1 that there is a close correspondence between the path of the body and the 'ridge' of most intense vertical magnetic field. These observations are therefore consistent with the body containing free magnetic dipoles of some kind.

Since the path of the body is a little offset from the line of vertical-component maxima, a capricious force such as a current of air is implied, which might also explain the retirement of the body. It seems reasonable to attribute to draughts the major action in moving the body, the initial entrance and wavering shape strongly suggest this. The living-room is large and well ventilated so that significant and very variable draughts might be expected at floor level given the rapidly-changing winds which would accompany a thunderstorm. Mrs Sale plainly regarded the body as being liquid because it had a surface with wavering blob-like outline and must have been denser than air.

No firm conclusions as to the nature of the body seem possible. The close association with lightning suggests that the strike was the prime cause. The body appears to have been denser than air, had a surface like a liquid, although it was non-wetting, and had a milky-blue luminous appearance. Its radiant energy was in the order of 2×10^{-4} W, observed for 15 s. Wind draughts seem to have been the dominant transport mechanism. From mapping the geomagnetic field we found a weak correlation between the motion of the body, and the regions of most intense vertical field, as would be expected if the body contained free magnetic dipoles or current loops.

Extensive underthrusting of undeformed sediment beneath the accretionary complex of the Lesser Antilles subduction zone

G. K. Westbrook, M. J. Smith, J. H. Peacock* & M. J. Poulter*

Department of Geological Sciences, University of Durham,
Durham DH1 3LE, UK

Along the eastern margin of the Caribbean Plate, which overrides the Atlantic oceanic lithosphere at ~20 km Myr^{-1} in an easterly direction[1], east of the Lesser Antilles island arc, lies a wide accretionary complex (Barbados Ridge Complex); 260-km wide at the latitude of Barbados and >20-km thick beneath Barbados[3,4], it increases in width and thickness from north to south[2] (Fig. 1). The style of deformation varies considerably along the eastern margin of the complex[2,3,5–11], and is related to the thickness and type of sediment on the Atlantic Ocean floor. A common feature is that a proportion of undeformed sediment from the ocean floor is brought beneath the deformed sediments of the accretionary complex, and in some areas a clearly defined seismic reflector separates the deformed and undeformed sediments, which has been interpreted as a decollement surface[5,12,13]. A seismic section from an investigation of the accretionary complex, conducted from RSS *Discovery* in 1980 using 12-channel seismic reflection and long range side-scan sonar (GLORIA), shows undeformed sedimentary rocks carried horizontally 74 km beneath deformed rocks forming the accretionary wedge. We report here that the low shear stresses required on the decollement between the deformed and undeformed rocks are made possible by porewater at pressures close to that of the lithostatic load.

The longest of three seismic profiles run across the eastern margin of the complex 50 km north of DSDP Leg 78A, Site 543 (X–X^1, Fig. 1) shows that a reflector with layered reflectors between it and the rough surface of the oceanic basement below, extends without significant interruption for nearly 45 km from the edge of the complex beneath a westward thickening wedge of material characterized by disturbed discontinuous reflectors (Figs 2 and 3). Beyond a region of disturbance, a reflector can be seen again continuing above the oceanic basement to the end of the section, some 74 km from the edge of the complex. This reflector and its apparent continuation are interpreted as a decollement, and the implication of this is that virtually undeformed sediment is carried on the ocean crust beneath the overlying accretionary complex for at least 45 km, and probably more than 75 km. Similar 'decollement' reflectors have been reported from other forearc accretionary complexes where sediment entering the complex on the ocean floor is of at least moderate thickness[17–19]. The previous greatest landward extent of such a reflector, 32 km from the edge of the accretionary complex[20], was demonstrated at the Nankai Trough off southern Japan. Extensive decollements are also well known in mountain belts on land[21–24].

It was the principal objective of DSDP Leg 78A in 1981 to drill through the accretionary complex near its leading edge, penetrating deformed sediment, the decollement, the undeformed sediment sequence, and finally the oceanic igneous basement[14–15]. Three sites were drilled on the northern flank of an oceanic basement ridge (the Tiburon Rise) where relatively shallow bathymetry and thin sediments provided favourable conditions (Fig. 1). The decollement was successfully reached in Hole 541, but poor drilling conditions prevented penetration of the undeformed sequence underneath.

The presence of a clearly recognizable decollement constrains interpretations of the formation of the accretionary wedge above it, because the thickness of sediment entering is known, and no further sediment is added from beneath, where the decollement is unbroken. This is important for calculations relating volume of the accretionary wedge and uplift of the surface to the rate of sediment input[25]. Currently, only the upper third of the sedimentary sequence on the Atlantic Ocean floor is added to the leading part of the complex, and if the decollement is stratigraphically controlled, a smaller proportion was added in the past.

East of the accretionary wedge, no clear difference can be seen in the character of the seismic section above and below the reflector which becomes the decollement, but drilling at Site 543 showed that it seems to lie at a change from Lower Eocene mud to radiolarian claystone, and also corresponds to an increase in the cohesion of the rocks from 40 to 100 kPa.

---

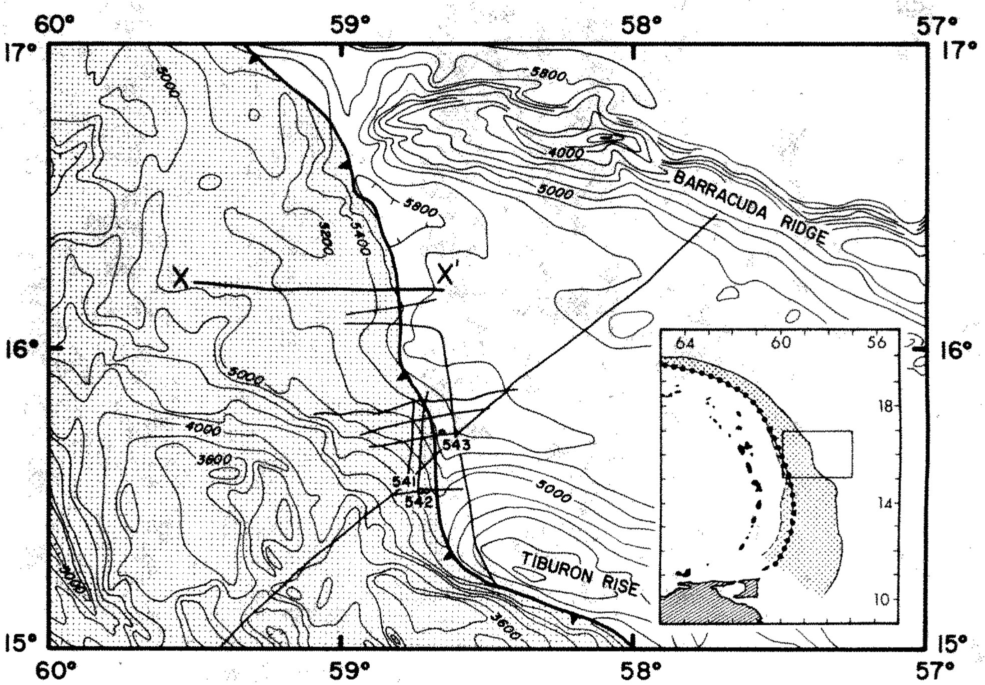

Fig. 1 Map of the front of the accretionary complex of the Lesser Antilles subduction zone, east of Guadeloupe. The area of the complex is stippled, and its front is shown by a heavy line. Also shown are multichannel seismic reflection lines including that shown in Figs 2, 3*a*, *b* (X–X′), and the drill sites from DSDP Leg 78A. Bathymetric contours are at 200-m intervals. The inset shows the area of Fig. 1 in relation to the whole of the accretionary complex (stippled) and the Lesser Antilles island arc (black island shapes). The axis of negative gravity anomaly is shown by dotted line.

0028-0836/82/500625—04$01.00

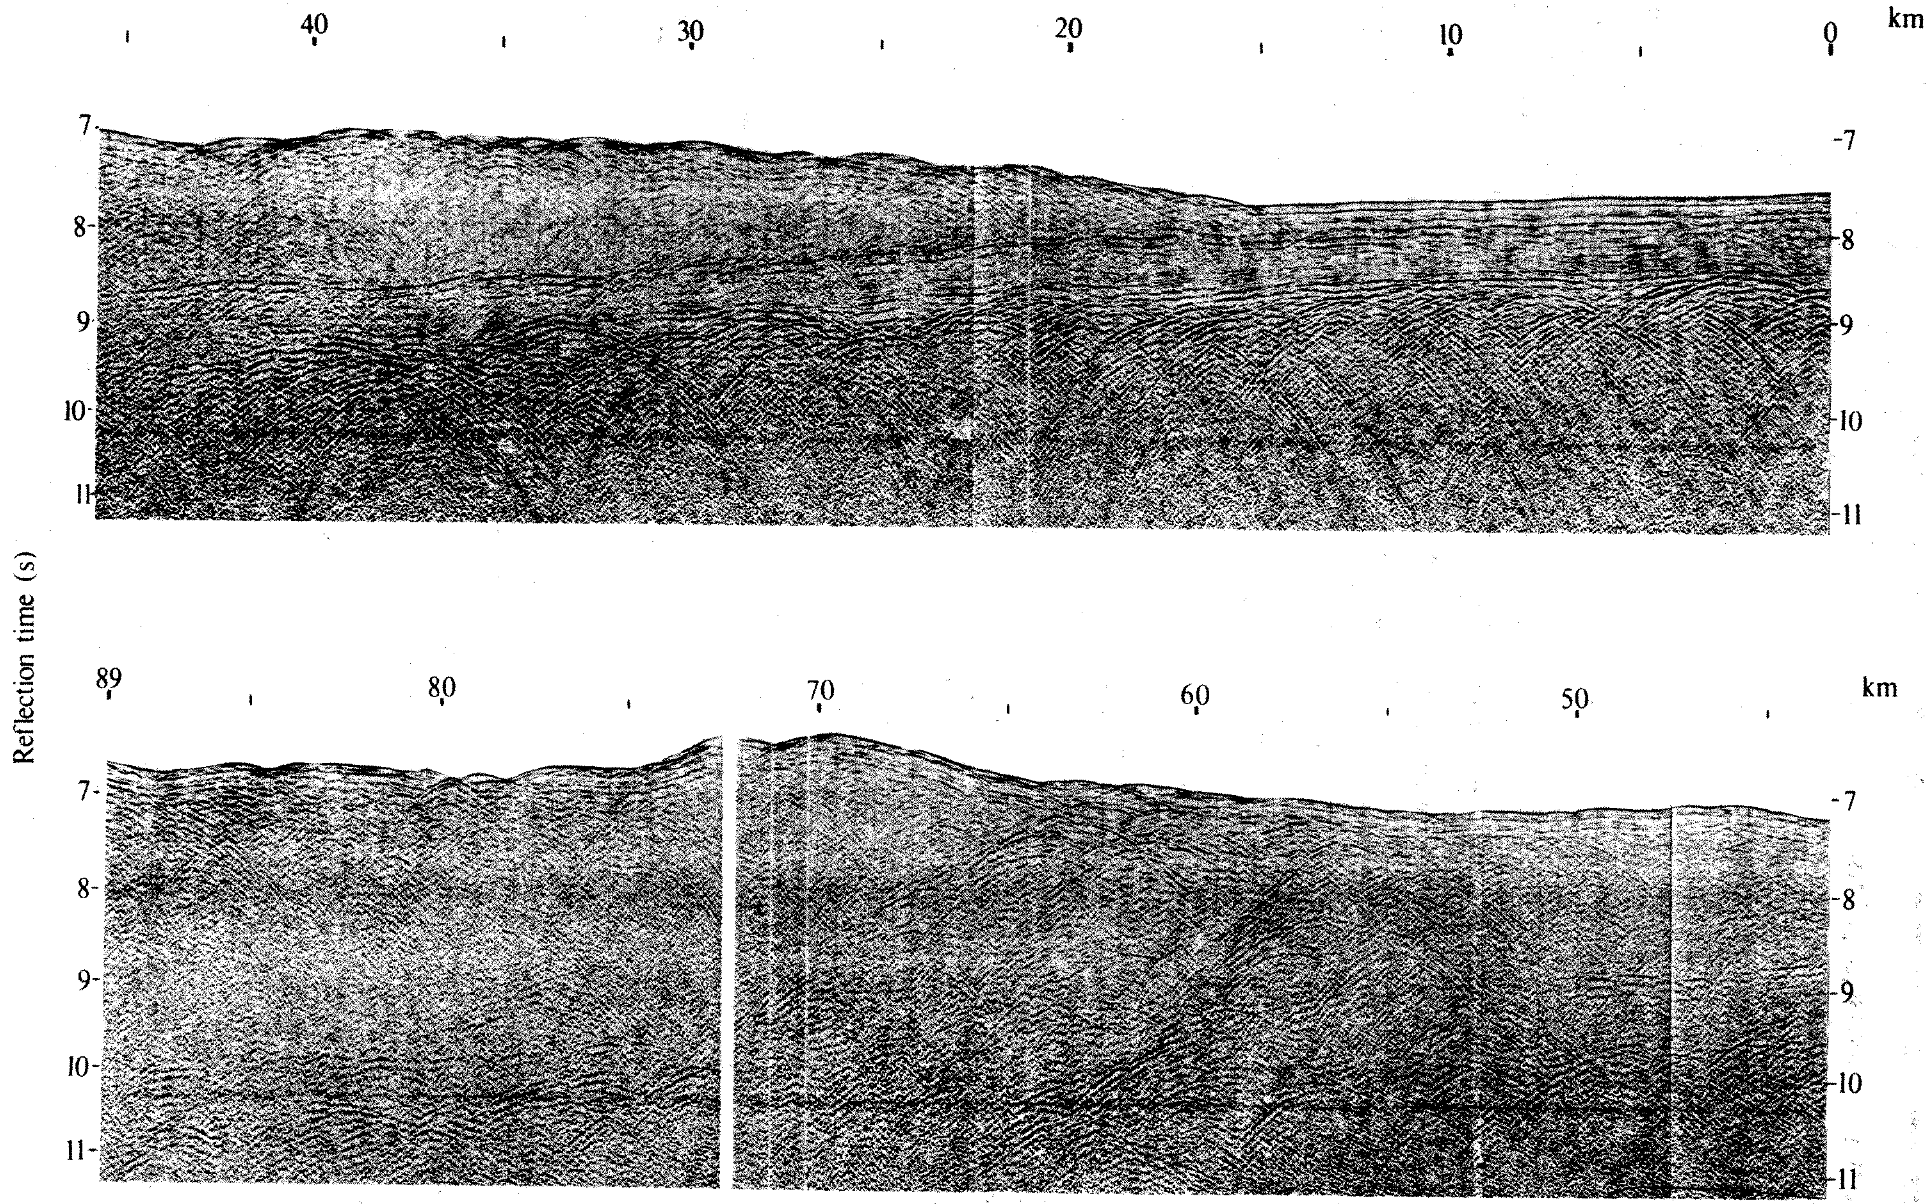

Fig. 2 A 12-fold stacked and deconvolved seismic reflection section across the front of the accretionary complex (X–X′ in Fig. 1). The oceanic basement can be seen beneath the complex, easily recognized from its rough surface which propagates prominent hyperbolae. Above this, another prominent reflector, interpreted as the decollement surface above a sequence of undeformed sediments, can be traced to nearly 60 km from the right-hand end of the section where it becomes obscure, but between 75 and 89 km it can be seen again above the basement, giving a total length of 74 km from the edge of the complex.

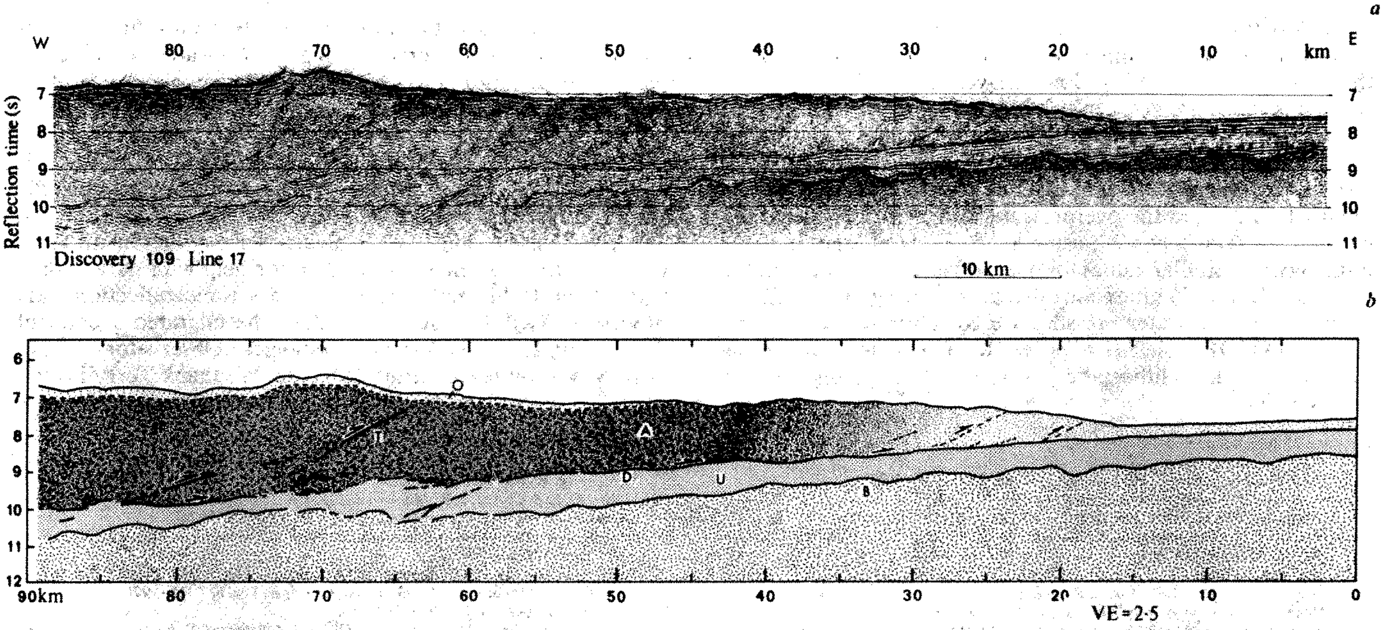

Fig. 3 *a*, Migrated version of Fig. 2. Most, but not all, of the more prominent reflectors have been highlighted. Of particular importance, apart from the basement and decollement, are the two prominent westward dipping reflectors, between 60 and 85 km from the right. They and other shorter dipping reflectors between 15 and 20 km from the right are interpreted as thrusts. *b*, An interpretational cross-section of the accretionary complex, based on Figs 2 and 3*a*. The wedge of accreted and deformed rocks (A) thickens rapidly over the first 25 km, where rapid compaction and movement along closely spaced thrusts, which are more abundant and closely spaced than the few depicted, appear to be the dominant deformational processes. The wedge retains a nearly constant thickness for another 20 km until it increases thickness again by movement along the widely spaced major thrusts (T), which produce uplift of the seabed. Beneath the decollement (D) sediment is undisturbed (U) until it reaches the region of the major thrusts, where some of it may be stripped off into the wedge. The dipping reflectors shown just above the basement (B) between 60 and 65 km are probably also reflections from a basement high slightly out of the plane of the section. Above the complex lies a thin layer of sediment (O) which was deposited directly on to it. The increase in the density of the ornament of the accretionary wedge reflects the inferred increase in density of the rocks, resulting from tectonic compaction. Vertical exaggeration of the relief of the seabed is 3.3 : 1. The average vertical exaggeration of features in the rocks beneath the seabed is 2.5 : 1.

The western end of the section is ~68 km east of the axis of the trough in the basement beneath the accretionary complex, revealed by gravity and seismic refraction data, where it is inferred that the ocean crust passes beneath the crystalline crust of the Caribbean Plate, and so it is not possible to say whether the layer of undeformed sediment is taken deeply into the subduction zone proper or stripped off and added to the base of the accretionary complex.

The rate of thickening of the accretionary wedge is greatest at the leading edge, where the angle of its taper is 5.4°, and decreases arcwards until, between 38 and 54 km from the right of the section there is very little significant increase in thickness with a taper angle of 1° (Fig. 3*b*). There are probably two main mechanisms for the initial thickening: imbricate stacking of small thrust slices, and direct horizontal shortening of the sediments accompanied by the expulsion of porewater during tectonic compaction. Thrusts with a vertical spacing of ~150 m were encountered at Sites 541 and 542 of DSDP Leg 78A, and their presence in the section is indicated by poorly defined westward dipping reflectors near the front of the wedge (Figs 2 and 3*a*). The small scale of the structures at the toe of the complex makes them difficult to recognize on the seismic section which, with a trace spacing of 50 m, does not resolve well reflectors shorter than 0.5 km. The initial thickening of the wedge will tend to reduce the deviatoric horizontal stress acting in the wedge, and it is probably accompanied by an increase in the strength of the rocks as they compact, so that ~22 km from the front some balance seems to be achieved with the rocks forming the wedge able to withstand the stress without any large increase in strain. Further significant thickening of the accretionary wedge seems to proceed by movement along much more widely spaced thrusts such as that seen some 50 km from the front of the wedge, but probably with little change in the strain of the rocks within the thrust slices (Fig. 3*b*). The point at which the wedge begins to increase in thickness again is also close to where the decollement first appears to suffer disruption.

There is little direct evidence on the state of compaction of the rocks forming the wedge. The rocks sampled at DSDP Sites 541 and 542 (refs 14, 15) showed a small but significant increase in density of ~13% from their equivalents at the reference Site 543 in the undeformed sequence in front of the complex, with an accompanying decrease in porosity, but no significant change in seismic velocity. An analysis of the stacking velocities used to produce Fig. 2 and the most effective velocities required to produce the migrated section of Fig. 3*a* was unable to determine any significant change in the seismic interval velocity of the rocks forming the wedge with distance from the front, other than what might be expected from the increase in thickness. This approach was of limited accuracy, however, because of the relatively small aperture of the seismic streamer compared with the depth of the reflectors, and so only a very strong lateral change in velocity is ruled out. A study of sonobuoy data in this area[23] also failed to show any strong lateral variation in velocity.

The small angle of taper between the top and bottom surfaces of the accretionary wedge and the low strength of the rocks forming the wedge and the underlying sequence[14,15], indicates that the shear stresses on the decollement must be very low[27–29]. The dynamics of a thrust wedge in which the stresses in the wedge exceed its strength have been analysed by Chapple[27], who derived the following relationship, where the angles of slope of the base and surface are small:

Shear stress at base of wedge
= Density × Gravity × Angle of slope of surface
× Thickness beneath a horizontal surface through the tip of the wedge
+ 2 × Yield stress of wedge × Angle of slope of base.

Applying this formula to the region of the wedge with a taper of 3° between 21 and 38 km, assuming that rocks are saturated with water but not overpressured, and behave as a Moho–Coulomb material with an angle of friction of 30°, the shear stress on the decollement is computed to be 0.44 MPa. This is much less than the 8.5 MPa expected from the load imposed by water saturated sediments and a coefficient of friction on the decollement of 0.85 (following Byerlee's law[30]). To reduce the stress, the porewater in the zone of the decollement must be overpressured[31] to value which is 0.97 of the load which would be imposed by the wedge if no water were present. If clay minerals reduce the coefficient of friction on the decollement[32] to 0.2, then the overpressure would be 0.81 of the dry wedge load. Davis *et al.*[29], using a different formulation, have obtained very similar values for overpressured porewater in the Barbados Ridge Complex and other accretionary wedges. These estimates of porewater pressure are corroborated by the discovery in DSDP Hole 542 of porewater at a pressure very close to that of the lithostatic load in the region of the decollement[14,15].

We conclude that this long decollement only functions as consequence of the overpressuring of porewater contained in the sediments forming the accretionary complex and undeformed sequence beneath it.

Rainfall over the Arabian Sea during the onset of the 1979 monsoon

David W. Martin & Michael R. Howland

Space Science and Engineering Center, The University of Wisconsin-Madison, Madison, Wisconsin 53706, USA

One path to understanding the summer monsoon of south-east Asia lies through its regimes of rain. There the main scales of interest range, on the small side, down at least to component rainstorms: that is, extending over hundreds of kilometres and lasting about a day. On the large side, interest might be extended to include the whole quasi-planetary monsoon system, although here, for practical reasons, the limits are taken to be 1 week and several thousands of kilometres. The main branch of the summer monsoon forms over the Arabian Sea. The rainfall of this sea, roughly 3,000 km in its dimensions, is known to us from about 40 coastal stations, mostly in India, plus six instrumented islands and the reports of seagoing ships. The ships stay mainly in a few lanes and in any case only record the frequency of rain, not the amount. Thus, even taken all together, these reports are hardly adequate for building a picture of the monsoon rains. We report here a new technique for inferring daily rainfall from visible or IR images obtained by a geostationary satellite, applied in a simplified form to the Arabian Sea during the onset of the 1979 summer monsoon. The rain area estimated increased spectacularly (from 1 to 14%) over a 1-week period coincident with the appearance of the Somali jet and development of the onset vortex.

Some scientists have exploited low-orbiting satellite observations of the Arabian Sea: C. S. Ramage, using visible imagery (personal communication), and Kidder and Vonder Haar and Rao *et al.*, using microwave data[1,2]. In each, the scale of the estimates—5 days or more—is too long to be of much use in portraying the monsoon through its development.

The 1979 Monsoon Experiment, which had an Arabian Sea component, may afford the best opportunity yet to build an evolutionary picture of the onset rains. The basis for this claim is the Indian Ocean Geostationary Operational Environmental Satellite (GOES IO). This satellite, positioned over the Equator at 60 °E, returned a visible and/or IR image, of 1–8 km resolution, once in almost every hour of the days from 11 to 21 June, a period which coincides almost perfectly with the onset of the 1979 monsoon.

To map daily rainfall over the Arabian Sea as the 1979 summer monsoon became established, drawing on several studies (see refs 3 and 4), we hypothesize the following: (1) four rainrates (nil, light, moderate and heavy) can be inferred consistently at any hour from a sequence of hourly visible or IR images; (2) the nil-rate class predominates; (3) most nil and heavy cases can be decided solely on the basis of brightness; (4) time change of brightness and pattern are important in the remaining cases; (5) most of the data in a single image are redundant; and (6) visible and IR data are complementary.

One special constraint follows from the enormous volume of data generated by the GOES IO imaging instrument; we cannot look at every element of every picture. In fact, this kind of problem could only be addressed by training a machine to take repeated measurements and make simple decisions.

The approach that has been taken is to imagine a network of gauges, distributed over the basin of the Arabian Sea. For each hour at each gauge a meteorologist, assisted by a computer, infers from satellite pictures whether the rainfall was light, moderate, heavy or nonexistent. The sum over 24 h of these rainrate class assignments yields an estimate $\hat{R}$ of the daily rainfall R. Thus, if $\hat{r}_i$, $i = 0, 1, 2, 3$, is the estimate of hourly rainfall attributed to the ith rainrate class and f_i is the frequency of the ith rainrate class over 24 h,

$$R \approx \hat{R} = f_0\hat{r}_0 + f_1\hat{r}_1 + f_2\hat{r}_2 + f_3\hat{r}_3$$

or, since $\hat{r}_0 \approx 0$

$$\hat{R} = f_1\hat{r}_1 + f_2\hat{r}_2 + f_3\hat{r}_3$$

Each $\hat{r}$ is a constant to be determined by multivariate least-

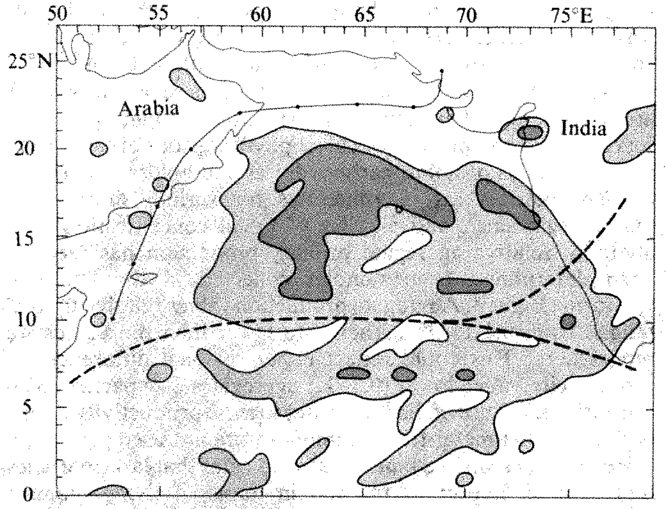

Fig. 1 Rain frequency for 17 June 1979. Stippling marks the grid points where rain was registered at least once during the day. The darker stippling shows where the heavy rain class was recorded at least once. Also shown are the axis of the Somali jet (dashed line) and the centre of the onset vortex (circle, at 16° N, 67° E), both from ref. 7 and the edge of the monsoon inversion (knotted line), from ref. 9.

squares regression of $\hat{r}$ on R, where R is measured by a gauge or radar.

Rain is estimated from a sequence of Earth-located (navigated), registered satellite pictures, each image of the sequence being spaced an hour or so from the others. There may be an IR sequence and a visible sequence or either alone. Images are displayed and analysed on the University of Wisconsin Man-computer Interactive Data Access System, McIDAS[5].

Rain has been estimated by this so-called grid history technique for the area from the Equator to 28° N and from 50° E to 79° E. Initially, the resolution of the grid across this area was 0.5°. It has since been relaxed to 1°. Eight days have been processed, 11–18 June 1979.

Applications of this technique to parts of the South China Sea and the eastern Atlantic Ocean when gauges or radars were present suggest values for the coefficients in the ratio of 1:4:10. So far it has not been possible to acquire enough ground observations of rain around the Arabian Sea to run the regression there. Thus, only rain class frequencies are presented here.

A photographic view of rain frequency for 17 June 1979 is shown in Fig. 1. At this stage of the monsoon, rain was extensive over the Arabian Sea but largely absent over India. A band of mostly light to moderate rain, centred near 7° N, angled north and north-west along the Malabar coast of India, then merged with a large mass of mostly heavy rain in the north-central part of the Arabian Sea. The Somali jet bisected the rain area between the upper and lower masses, and the edge of the rain region lay 200–400 km east and south of the edge of the monsoon inversion.

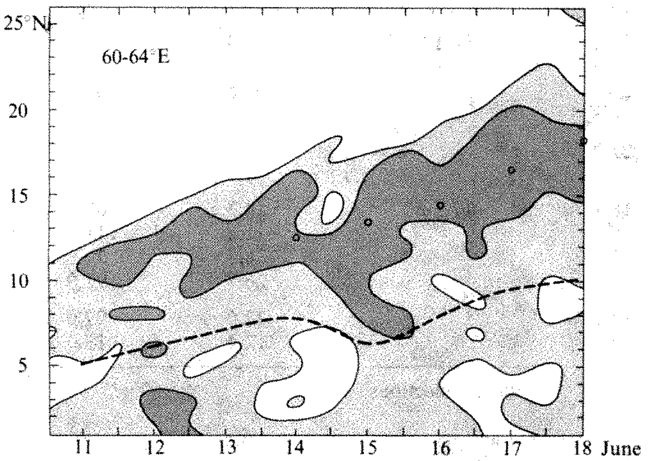

Fig. 2 Time–latitude section of rain frequency averaged over a strip from 60 to 64° E. The convention is the same as for Fig. 1.

Time changes in rain class frequency averaged across a longitudinal strip through the centre of the Arabian Sea (60–64° E) are shown in Fig. 2. Quite consistently, the heavier rain occurred on the north side of the rain area, to the left of the axis of the jet. The rain area spread steadily northwards, at ~150 km day^{-1}, or twice as fast as the northward movement of the jet axis.

It is expected from simple jet stream dynamics[6] that over the Arabian Sea, rain would be heaviest to the right of the axis of the Somali jet. The departure observed here is apparently due to low level convergence occurring with the onset vortex, a cyclone which first appears on 14 June in the 850-mbar analyses of the atlas of Krishnamurti *et al.*[7] The possibility has been suggested[8] that the onset vortex received kinetic energy through baroclinic processes (as well as barotropic processes), perhaps even during its formation. Figures 1 and 2 tend to confirm this, by showing first, a concentration of rain—implying ascent and release of latent heat—in the north-west semicircle of the storm, which available temperatures and winds indicate was the warmer half between 850 and 700 mbar, and second, the presence of heavy rain at least 2 days before the vortex was detectable in low level winds.

For the Arabian Sea as a whole, the percentage coverage by rain of light, moderate or heavy rain classes is shown in Fig. 3.

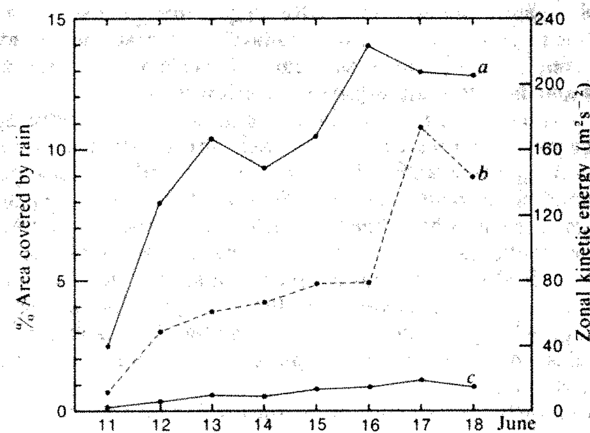

Fig. 3 Rain coverage over the Arabian Sea from 11 to 18 June. Each point is an average over the hours from 00.00 to 23.00 GMT. *a*, All rain classes. *c*, Heavy rain class only. *b*, Values of area-averaged zonal kinetic energy, from ref. 8.

The change over these eight days is remarkable: from 1% on 11 June to 14% on 18 June. The contribution of the heavy rain class to this growth is also shown in Fig. 3, from 0 to 1%. For heavy rain especially, the coverage curves closely parallel changes observed by Krishnamurti *et al.*[8] in zonal kinetic energy averaged over the Arabian Sea, suggesting that the convective response of the atmosphere to accelerations of the low level flow was relatively fast.

We conclude that the technique described here can provide information on the changing pattern of rainfall over the Arabian Sea through the onset phase of the summer monsoon. The precise limits of its accuracy remain to be established.

During the 1979 onset a near-equatorial belt of rainfall spread northwards across the centre of the Arabian Sea. Heavy rains developed, in association with an onset vortex, on the north flank of the Somali jet and moved north as the jet moved north.

Marine snow: major site of primary production in coastal waters

G. A. Knauer, D. Hebel & F. Cipriano

Moss Landing Marine Laboratories, Moss Landing,
California 95039, USA

Fragile aggregate particles, or 'marine snow', were collected by SCUBA from coastal surface waters using trace metal-free techniques, and their primary production (rates of photosynthesis by associated phytoplankton) was determined relative to corresponding water column production. Primary production associated with these particles was found to range from 11 to 58% of total production, indicating that large particles can have an important role as major sites of primary production in the marine environment. Our results suggest that the use of water bottles to collect samples for productivity measurements may not sample large particles adequately in certain conditions, and thus may lead to underestimates of primary production.

Macroscopic aggregates in the millimetre–centimetre size range are a common feature of the pelagic ecosystem. Compositionally, 'marine snow' is very complex and includes both organic and inorganic materials. Several origins for these amorphous aggregates have been suggested: adsorption of dissolved and colloidal carbon onto bubbles or other surfaces[1]; mucus flocs derived from various zooplankton such as the houses of larvaceans[2] or mucus webs produced by pseudothecomatous pteropods[3]; agglutination of fecal material or zooplankton remains[4]; or mucus colonies or mats formed from various types of phytoplankton.

Because of their fragile nature, the use of conventional collection techniques (such as nets or water bottles) has usually resulted in disruption of these systems such that direct study was precluded[5]. Recently, techniques involving direct hand collection of marine snow in conjunction with SCUBA[6,7] have provided relatively undisturbed samples of these particles which are amenable to laboratory analysis. Macroscopic aggregates serve as enrichment sites for chlorophyll[6], various organic compounds such as proteins, carbohydrates and lipids[7], microscale nutrient patches[8] as microhabitats for various micro- and macro-organisms[9], and as sites of metal concentration[10]. In addition, relative aggregate primary production has recently been determined from samples collected in the southern California Bight[11]. Aggregate production values relative to total ranged from 0.1 to 9%. These are lower than the values we report here. This could reflect either regional differences in productivity, much lower (0.1–1.1 aggregates l^{-1}) particle concentrations, the use of distilled water to rinse productivity filters, or the fact that metal-free techniques were not used.

Recent work with sediment traps indicates that large particles represent an important fraction in terms of living biomass throughout the water column[12]. These large particles are not typically collected using water bottles[13,14], and can only be collected using sediment traps (except in surface waters where some sampling by SCUBA is possible). Because of the large particle–living biomass relationship, and because water bottle collections do not adequately sample such large particles, we felt that a significant portion of phytoplankton primary production (given the biological and chemical associations) may be overlooked. We therefore collected large particles from the euphotic zone to determine their associated rates of primary production relative to 'ambient' (that is, containing no large particles) water from the same depth. Further, we compared these results with samples collected by standard procedures which involved water collection bottles.

Samples of marine snow were collected from two stations in the area of Monterey Bay, California in June and July 1981 from a depth of 10 m using SCUBA techniques similar to those devised for open-ocean blue-water diving[5,6]. Aggregate abundance (Table 1) was determined using a 2.3-cm diameter loop mounted on a TSK flowmeter[6]. As is often the case with marine snow particles, particle size at a given station was remarkably homogenous. Aggregates from the June collections were all relatively large and well formed, while aggregates collected in July were smaller, more loosely consolidated, and appeared to be in an earlier state of development. Note that stringent anti-contamination methods were used during all phases of sample collection and manipulation[10,15,16], as significant reduction in primary production measurements can occur from metal

contaminants[16]. Aggregates were collected in 3–7 m lengths of acid-cleaned 9.5 mm diameter Bev-A-Line tubing. Before collections, the ends of the collection tubes were connected to form a continuous loop and placed into acid-cleaned plastic bags to avoid contamination. Polyethylene gloves were worn underwater while sampling and aggregate collection was directed into any perceivable current to avoid diver-related contamination. Sampling tubes were filled with either 15 (July collection) or 25 (June collection) aggregates per tube. In addition, at each station four tubes were filled with ambient seawater only, to assess the productivity of this fraction and also to correct for the inclusion of ambient seawater in the aggregate collection tubes. After collection, each sampling tube was reconnected, placed in its respective plastic bag, and returned to the ship for processing. Aboard ship, the contents of each tube (four tubes containing aggregates and ambient seawater and four tubes containing only ambient seawater) were emptied into 250 ml acid-cleaned polycarbonate flasks, injected with 10–20 μCi $H^{14}CO_3^-$ and incubated for 3 h in a seawater cooled deck-top incubator designed to simulate light levels at 10 m. Following the incubation period, samples were filtered and the filters counted by liquid scintillation to determine the amount of photosynthetically fixed carbon. The primary production procedure used followed clean techniques described in ref. 16.

At the same time as particle collection, water samples from each station were obtained from a depth of 10 m using standard 5-l Niskin bottles. These had been modified and acid cleaned to preclude metal contamination and mounted on non-metallic synthetic hydroline[17]. Incubation, processing and counting of these samples followed the same procedure described above for the aggregate samples.

The results are presented in Table 1. It is obvious from the fractional production data that aggregate contribution to primary production can represent a significant portion of the total production. Thus, during the June sampling period when the aggregates appeared well formed and rather abundant (11.5 aggregates l^{-1}), >50% of the total production was associated with these particles. In contrast, during the July sampling period, the aggregates were less concentrated (6.6 aggregates l^{-1}), more loosely consolidated and probably in an earlier stage of development. Here, the aggregates contributed relatively less to total production with values ranging from 11 to 38%.

Another interesting aspect of this study, and a potentially serious problem, involves comparing total primary production derived from hand-collected samples with Niskin bottle collections (Table 1). It is apparent that, depending on the kinds of particles present in the water column, significant errors can result due to the failure of the bottles to sample the particle field adequately. For example, during the June sampling period, primary production calculations derived from Niskin bottle samples could have underestimated production by 40% (Niskin production = 62% of the total fractionated production). However, in July, when the particles were less consolidated, there was no significant difference between SCUBA and bottle-collected samples. Thus, experimental design flaws of this sort can not only lead to underestimates of this important parameter, but may also contribute to overall sampling variability.

For an accurate understanding of primary productivity processes in marine ecosystems, it is imperative that the role of large particles as well as efficient procedures for sampling these particles be established.

We thank the captain and crew of RV *Cayuse* for help and John Heine for diving assistance during our Cobalt I cruise. This research was supported by grants from the NSF Biological Oceanography (OCE 79-09431) and Marine Chemistry programmes (OCE 80-03200).

Tulu Bor Tuff at Koobi Fora correlated with the Sidi Hakoma Tuff at Hadar

Francis H. Brown

Department of Geology, University of Utah, Salt Lake City,
Utah 84112 USA

The Hadar Formation of Ethiopia is renowned for its superb mammalian fossils, but there is still some doubt about the age of the Hadar faunas and their relations to faunas from other sites despite intense efforts to date the Hadar material[1,2]. Here I report a stratigraphical tie between the Hadar Formation and formations in the Lake Turkana region, which helps to relate fossil faunas from the two areas.

The fossil site of Hadar is located along the lower reaches of the Awash River; the Shungura and Usno Formations are located in the lower Omo valley north of Lake Turkana, and the Koobi Fora Formation is located on the north-east side of that lake. The fossiliferous formations of the Lake Turkana region have many tuffs in common, and probably derive from a single depositional system dominated by the Omo River[3,4]. The Awash River and the Omo River have a common drainage divide for a distance of ~100 km through the Guraghe Mountains northwards to Badda Rogghie. According to Mohr[5], the Guraghe Mountains "are composed solely of silicic lavas and tuffs except for the summit line which is formed of superimposed massive trachyte". The age of these lavas and tuffs is unknown, but if volcanoes in the general region of Mt Guraghe erupted during the Plio-Pleistocene, eruptive products might have found their way both to the lower Awash Valley, and into the Lake Turkana Basin.

A prominent tuff in the Koobi Fora Formation is the Tulu Bor Tuff, which is correlative with Tuff B of the Shungura Formation, and Tuff U-10 of the Usno Formation[3]. These tuffs are of normal polarity, and are thought to lie in the lowest normal part of the Gauss Normal Epoch, thus having an age between 3.17 and 3.42 Myr (ref. 6). Two minor chemical variants of the Tulu Bor Tuff have been recognized, which correspond to Tuff B-α and Tuff B-β of the Shungura Formation[3]. Walter[1] provides analyses of shards from the Sidi Hakoma

Table 1 Comparative analyses of the Sidi Hakoma Tuff and Tulu Bor Tuff microprobe analyses of major and minor elements (wt %)

	Sidi Hakoma range	Tuff* average	β-Tulu Bor Tuff†
SiO_2	71.70–73.23	72.54	71.69
TiO_2	0.12–0.24	0.16	0.14
Al_2O_3	12.16–12.60	12.37	11.92
Fe_2O_3‡	1.24–1.48	1.33	1.39

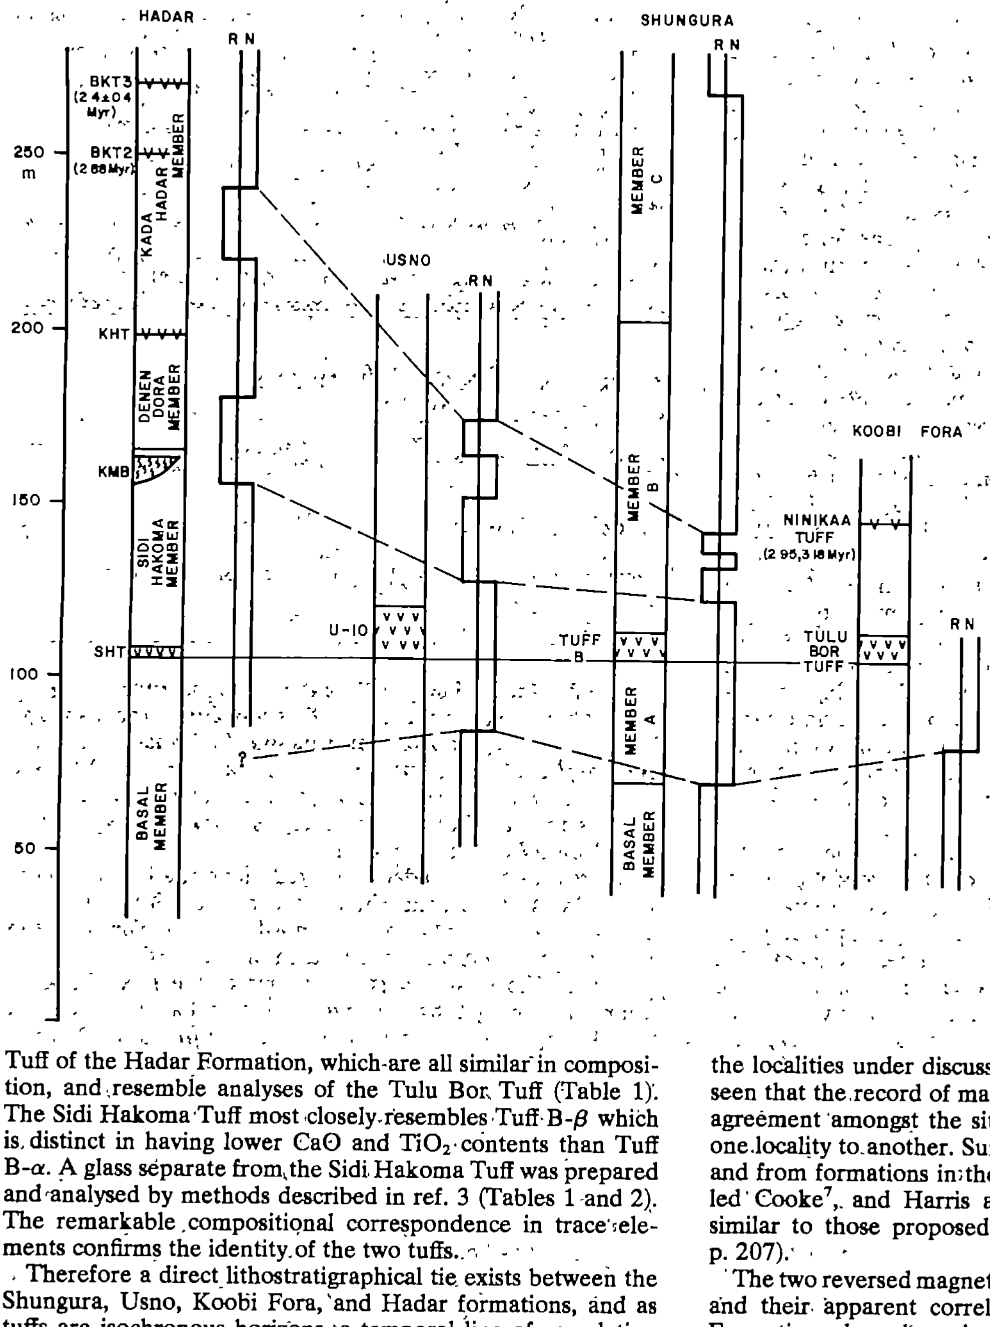

Fig. 1 Schematic partial stratigraphical columns for the Hadar, Usno, Koobi Fora and Shungura Formations. The magnetic polarity log for the Koobi Fora Formation is from ref. 13.

Tuff of the Hadar Formation, which are all similar in composition, and resemble analyses of the Tulu Bor Tuff (Table 1). The Sidi Hakoma Tuff most closely resembles Tuff B-β which is distinct in having lower CaO and TiO_2 contents than Tuff B-α. A glass separate from the Sidi Hakoma Tuff was prepared and analysed by methods described in ref. 3 (Tables 1 and 2). The remarkable compositional correspondence in trace elements confirms the identity of the two tuffs.

Therefore a direct lithostratigraphical tie exists between the Shungura, Usno, Koobi Fora, and Hadar formations, and as tuffs are isochronous horizons, a temporal line of correlation also extends to each of these localities. Schematic sections of the localities under discussion are shown in Fig. 1, where it is seen that the record of magnetic polarity transitions is in good agreement amongst the sites, although thicknesses vary from one locality to another. Suid fossils from the Hadar Formation and from formations in the Lake Turkana Basin have already led Cooke[7], and Harris and White[8] to suggest correlations similar to those proposed here (not as misquoted in ref. 9, p. 207).

† Sidi Hakoma Tuff.
‡ β-Tulu Bor Tuff, Area 117, Koobi Fora.

The two reversed magnetozones above the Sidi Hakoma Tuff, and their apparent correlatives in the Shungura and Usno Formations, have been independently identified as the Mammoth and Kaena Events[6,10]. Such identifications are consistent with all K/Ar and fission-track ages from the Hadar Formation with the exception of the 3.6-Myr age on the Type B Kadada Moumou Basalt (KMB). The mean of all ages on the Type A KMB is 3.01 Myr, which when corrected upward by 3.5% (see statement in ref. 11) would be 3.12 Myr, in concordance with its reversed polarity. These identifications are also in accord with K/Ar dates on tuffs from the Lake Turkana Basin except for the dates on Tuff B-10 of the Shungura Formation, which are apparently too old (see ref. 6).

As most of the fossil material at Hadar derives from levels between the Sidi Hakoma Tuff and BKT-2 (see Fig. 1), which is only a few metres above the top of the Kaena Event, these faunas must correlate with faunas from the lower part of Member B of the Shungura Formation, and with those of the Usno Formation. It is likely that these faunas all lie between 3.3 and 2.8 Myr in age. This chronology is consistent with the palaeomagnetic record at Hadar and in the Lake Turkana Basin, with the suid evidence, and with all radiometric age determinations except those noted above. The mean sediment accumulation rate for the interval between the Sidi Hakoma Tuff and BKT-2 is ~35 cm kyr^{-1}, which is also reasonable. The ages on the Type B KMB are evidently too old, but this discrepancy has not yet been explained.

I thank Drs J. Aronson and R. Walter for supplying tuff samples, Drs R. Drake and G. Curtis for permission to use an unpublished date on the Ninikaa Tuff, and Drs W. T. Parry and J. M. Harris for reading the manuscript in its preliminary form. Financial support for analytical work was provided by NSF grant BNS-8007354.

Faunal age of the Usno, Shungura B and Hadar Formations, Ethiopia

N. T. Boaz*, F. C. Howell† & M. L. McCrossin*

* Department of Anthropology, New York University, New York, New York 10003, USA
† Department of Anthropology, University of California, Berkeley, California 94720, USA

Recent work by Brown[1], correlating the Sidi Hakoma (or Sidiha Koma[2]) Tuff at Hadar with Tuffs B and U-10 of the Shungura and Usno Formations, respectively, reverses a recent finding[3] indicating an age of the Hadar Formation fauna of 2.9 to greater than 3.6 Myr BP. The difference in these determinations is 0.4 Myr, a significant period of evolutionary time. We compare the faunas from Shungura Unit B10, Usno and Hadar and discuss the implications for interpretation of the early hominid fossil record.

The fauna from Member B of the Shungura Formation derives primarily from the uppermost units, particularly Unit B10, superjacent to the B10 Tuff dated at 3.03 ± 0.07 Myr BP[4]. The faunal sample from White Sands and Brown Sands localities of the Usno Formation, which has been correlated with lower Member B (Unit B2), is situated stratigraphically near Tuff U10 dated at 3.05 ± 0.30 Myr BP[4] and above the basalt of U1 dated at 3.39 ± 0.23 Myr BP[4]. The Shungura B10 fauna occurs above the top of the Kaena Event (2.92 Myr BP), and the Usno fauna straddles the bottom of the Mammoth Event (3.15 Myr BP) but is younger than the Gilbert–Gauss boundary at 3.4 Myr BP[5]. Using the K/Ar and palaeomagnetic determinations to estimate best-fit ages of 2.92 and 3.15 Myr BP for B10 and Usno/Lower B faunas, respectively, it is clear that they are separated by ∼0.2 Myr. Considerations of the age of the Shungura Member B fauna therefore must include a realization that there is significant time difference between upper (B10) and lower (B2) portions of the member, the latter equivalent in time to Usno.

Table 1 gives large mammal species lists for Shungura B10, the Usno Formation and the Hadar Formation, compiled from published sources[6–13], the Omo faunal catalogue and our own interpretations, except where indicated. Table 2 summarizes results from six faunal similarity coefficient calculations. By any method the Usno and Hadar faunas are more similar than are Shungura B10 and Hadar faunas, thus indicating a probable age for Hadar nearer to 3.15 Myr BP than to 2.92 Myr BP.

Comparison of similarity coefficients based on presence or absence of taxa at Hadar with faunas in the range 3.2–4.0 Myr BP, such as at Laetoli, Kanapoi, Mursi and Ekora, is hindered by the small and not fully studied or published faunal inventories from the latter sites. However, by a consideration of evolutionary stages of single taxa, particularly in this case, those at Hadar not shared with Usno, biostratigraphical evidence can be obtained. The species not shared are: *Parapapio* cf. *jonesi*, *Theropithecus darti*, *Canis* aff. *mesomelas*, *Pachycrocuta* aff. *perrieri*, *Loxodonta adaurora*, *Elephas recki brumpti* (ex-'Stage 1'), *Ceratotherium* cf. *praecox*, *Kolpochoerus afarensis*, *Giraffa stillei*, *Praedamalis deturi*, and *Madoqua* ?*avifluminis*. Unshared generic identifications at Hadar of potential biostratigraphical importance are *Mammuthus* sp., *Ugandax* sp. nov., ?*Pelorovis* sp. and Ovibovini sp. aff. '*Bos*' *makapaani*.

The first four species listed and *Elephas recki* occur in the South African middle to late Pliocene site of Makapansgat[14], as do three other shared Hadar-Usno species. Unshared '*Bos*' *makapaani* from Buffalo Cave, Makapansgat may be of similar age. *E. recki* and ?*Pelorovis* sp. are Hadar taxa not shared with Usno but present in the later Shungura B10 fauna. *Hipparion afarense* is more primitive than *H. ethiopicum*, which first occurs in Shungura Formation Member C, but is more advanced (and apparently later in time) than *H. sitifense* found in both Shungura B10 and Usno faunas[16]. *Loxodonta adaurora* and *Ceratotherium praecox* occur in the Omo Mursi Formation, at ∼4 Myr BP[7]. Cooke[9] has discussed *Kolpochoerus afarensis* as ancestral to, but especially as seen in the larger specimens, very similar to *K. limnetes*, found in Usno and B10 assemblages. *Giraffa stillei*, although known from Laetoli, is considered by Churcher[17] to range from the "?early Pliocene to early middle Pleistocene" and it may prove synonymous with *G. gracilis*, present at Usno and Shungura B10. Gentry[10] considers *Praedamalis deturi* suggestive of "an older age than Shungura upper Member B" and Hadar *Madoqua* ?*avifluminis* similar to specimens from the Ndolanya Beds at Laetoli. The Ndolanya Beds are dated to between 2.41 ± 0.12 and 3.49 ± 0.12 Myr BP[18], in the same age range as the Usno Formation. The genus *Mammuthus*, with three recognized species, ranges in Africa from the Pliocene to the early Pleistocene[19]. *Ugandax* sp. is "no later than Shungura upper B and probably earlier"[11].

The faunal similarities with Makapansgat, with Shungura B10 and the presence of *Hipparion afarense* are suggestive of an age younger than the Usno Formation, while *Loxodonta adaurora*, *Ceratotherium praecox*, *Kolpochoerus afarensis* and perhaps *Giraffa stillei* suggest an older age. The bulk of the diagnostic fauna, however, is consistent with an Usno/Shungura lower B age for the Hadar fauna.

This finding has several implications for interpretation of the fossil hominids from the Hadar Formation. Because the fossil-bearing Hadar Formation is constrained between SHT (∼3.2 Myr BP, based on ref. 1) on the lower end and BKT-2 (2.88 ± 0.08)[3] and the top of the Kaena Event (∼2.92 Myr BP) on the upper end, the hominids are relatively closely spaced in time. There are not more than some 300,000 yr between hominids at the top and bottom of the sequence.

The temporal correlation of Pre-Kadada Moumou (or Kada Damoumou[2]) Basalt Hadar hominids with Laetoli hominids[3] (dated now between 3.49 ± 0.03 Myr BP and 3.76 ± 0.03 Myr BP[17]) is called into question. There may be between 0.3 and 0.9 Myr difference in time between the two parts of the type-series of *Australopithecus afarensis*[20].

The similarity in time between Hadar hominids and those from Makapansgat may be closer than suspected[21]. Not only does Hadar now appear later in time, but several indications seem to place Makapansgat earlier. Cooke[14] records from this site *Notochoerus capensis*, also known from the 'Kubi Algi' Formation and possibly Kanapoi[22], both apparently near 4 Myr BP, and *Potamochoeroides shawi*. The latter is termed *Metridiochoerus andrewsi* (I) by Harris and White[23] but Cooke[22] regards it as a South African endemic Pliocene suid not particularly useful for biostratigraphical correlation. Cooke[14] does not recognize at Makapansgat the typical *Metridiochoerus andrewsi* which is found in Shungura Member G (not as reported in ref. 21). An additional indicator for the 'old' age at

Compiled from refs 6–13. *, Identification by E. Delson, ⁺, identification by G. G. Eck. Hominid taxa and identifications above the subfamilial or tribal level are not included. For the purposes of calculating the similarity coefficients in Table 2, qualified species identifications (cf., aff. and ?) have been counted as occurrences. Identifications to genus only are not counted in calculations.

Table 2 Faunal similarity coefficients among Hadar, Usno and Shungura B10 faunas

Faunal comparison	Hadar–Usno	Hadar–Shungura B10	Usno–Shungura B10
Simpson (C/N_1)	0.61	0.35	0.88
Jaccard $\left(\frac{C}{N_a+N_b-C}\right)$	0.28	0.20	0.53
Kulczynski $\left(\frac{C(N_a+N_b)}{2N_aN_b}\right)$	0.48	0.33	0.73
Burt-Pilot $\left(\frac{2C}{N_a+N_b}\right)$	0.44	0.33	0.69
Otsuka $\left(\frac{C}{\sqrt{N_aN_b}}\right)$	0.46	0.33	0.71
Braun-Blanquet $\left(\frac{C}{N_2}\right)$	0.35	0.32	0.57

Formulae are from ref. 26. N_a and N_b are observed number of species in the two assemblages, C is the number of species in common, N_1 is the smaller and N_2 the larger of N_a and N_b.

Makapansgat is a recent report by Lehmann and Thomas[24] that the Makapansgat bovid, *Redunca* aff. *darti* also occurs in an upper level of the basal Pliocene Sahabi Formation, Libya. *Nyanzachoerus kanamensis*, a species found at Hadar and Usno, occurs in this same level at Sahabi[25]. Thus it is far from clear that Makapansgat *Australopithecus africanus* post-dates Hadar *A. afarensis*. Hadar and Makapansgat may be broadly equivalent in faunal age to the Usno Formation, although Makapansgat probably ranges later in time.

Because of the poor knowledge of African faunas in the 3.2–4.0 Myr BP time range, it is difficult to reject categorically a pre-Usno age for Hadar. Nevertheless, our results are consistent with the age suggested by Brown[1] for the SH Tuff at Hadar.

We thank E. Delson, G. G. Eck, D. Boaz and F. H. Brown for discussion and assistance.

Evidence that seals may use echolocation

Deane Renouf & M. Benjamin Davis

Department of Psychology, Memorial University of Newfoundland,
St John's, Newfoundland, Canada A1B 3X9

Harbour seals (*Phoca vitulina*), like many phocid species, forage to some extent at night[1]. Although nocturnal mammals typically rely on non-visual sensory channels, seals have adapted to low light levels by sharpening their visual sense[2]. Although enhanced visual sensitivity would be functional in clear water, many species inhabit turbid coastal or estuarine regions where vision is sometimes of limited use even in daylight. Here we present experimental evidence in support of the contention that when visual cues are not available, seals use echolocation. Our results help to explain why previous attempts to demonstrate sonar abilities in pinnipeds have been unsuccessful.

Circumstantial evidence suggests that pinnipeds use some form of echolocation. Some species produce click vocalizations similar to the signals of animals that are known to have a sonar system[3]. Harbour seals click more frequently in the dark[4] and there are numerous reports of blind seals functioning sufficiently well to raise a pup[5]. However, all experimental evidence has been negative. Evans and Haugan[6] reported that although a sea lion (*Zalophus californianus*) was able to retrieve rings at night, no vocalizations were recorded, and the animal refused to perform when blindfolded. Schusterman[7] tried to train *Zalophus* to discriminate between visually identical plexiglass disks, one filled with air, the other solid so that each disk would return a different echo to the animal. After over 2,000 trials the sea lion was unable to distinguish reliably between the targets, even though click trains were recorded on most trials. Scronce and Ridgway[8] trained a blindfolded grey seal (*Halichoerus grypus*) to retrieve a ring, and later presented the seal with the task of discriminating between two differently sized styrofoam surfaces. These authors concluded that the seal was not using sonar because few clicks were recorded during retrieval, and because the animal, having produced no vocalizations, was unable to learn the styrofoam discrimination.

Our recordings in the field[4] and from captive animals indicate that harbour seals produce at least two types of signals. The first is a brief, rapid-onset pulse which is emitted either as a single click or as a doublet (see Fig. 1*a*). Because of its fast onset, the click spans the entire audio spectrum, however most of the energy lies near 7.5 kHz. The second signal consists of a train of these clicks emitted in rapid succession such that the interval between each one determines the overall pitch of the burst (see Fig. 1*b*).

At Miquelon (45° 45′ N, 56° 14′ W) where there is a breeding colony of *P. vitulina*, we found that both vocalizations were

0028-0836/82/500635—03$01.00

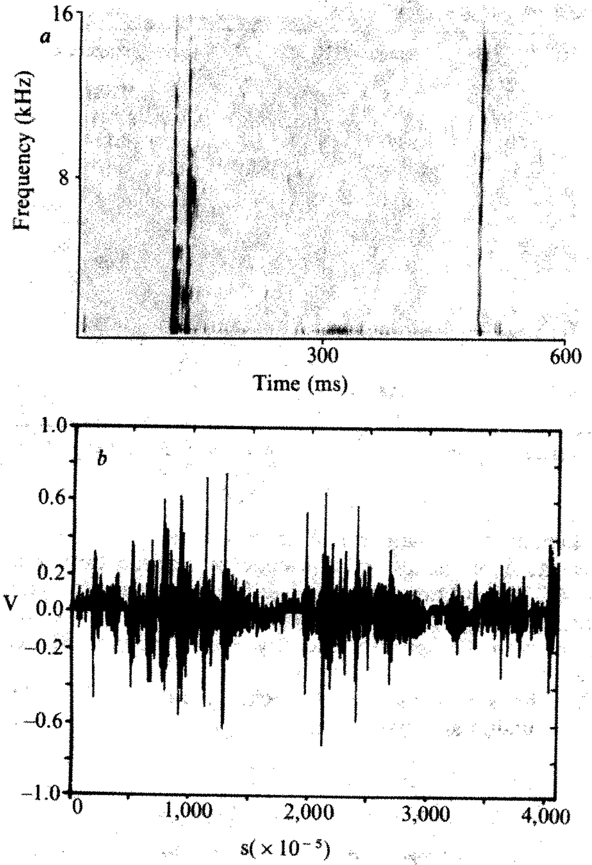

Fig. 1 *a*, A sonagram of a single and a doublet click made by the seal during discrimination training. *b*, Waveform of a train of clicks recorded from a breeding colony of harbour seals at Miquelon.

more frequent at night. However, before the present experiment, our captive harbour seals would only click when given live fish in total darkness. In early attempts to use Schusterman's procedure[7] with a harbour seal, we found that the animal would not click in the presence of the disks, perhaps because it had no understanding of the fact that echoes might be of assistance. We then modified the method to enhance the likelihood that the seal would use sonar to solve a similar discrimination problem.

The subject of the experiment was a 7-yr-old male harbour seal who has lived in captivity since it was collected as a weaned pup. The apparatus consisted of two rings made of hollow black plastic tubing, 4 cm in cross-section. The inner diameter of each ring was 9 cm, and the outer diameter 17 cm. One ring was internally ballasted with 600 g of lead; the other contained 101 g of lead and was filled with water. Both rings were negatively buoyant and during the second phase of the experiment were suspended 0.5 m apart in the water by 1 m-long strings such that the ballast lay at the bottom of each ring. The string of the air-filled ring had a small loop at its free end so that we could distinguish between each ring during testing.

The study was done in an outdoor 7.5-m diameter tank above ground, constructed from 6.5-cm white pine. It was filled with seawater to 1.2 m depth. For certain parts of the experiment a black vinyl tarpaulin, suspended over a superstructure ~1 m above the tank, was draped to the ground so that we could work under it.

A Gould model CH-17U hydrophone was used to monitor vocalizations. During the second phase of the experiment it was positioned at the same depth as the rings, ~1.5 m to the side of the nearest ring. Signals were recorded with a Sony model TC-D5 cassette tape recorder, and a Racal Store 4 instrumentation recorder was used to determine any ultrasonic components.

The seal was trained to retrieve the air-filled ring to earn a piece of herring. The ring was slipped into the water on one side of the tank, while the seal waited, with its head out of the water, at a station on the opposite side until one of us said "fetch". The seal then located the ring, put its snout through the centre and in this way carried it back to the experimenter and tossed it over the side. Once the animal was able to do this, it was required to do so at night when the tarpaulin was in place to eliminate ambient light. We recorded the latency between the "fetch" call and the moment when the seal returned with the ring.

After seven sessions of 10 trials each, the seal was then presented with two rings, and required to retrieve the air-filled one. In this case, one experimenter held the free end of the strings to suspend the rings ~0.6 m below the water surface, ~0.8 m away from the tank wall. When the seal chose the air-filled ring, it was released and the animal brought it across the tank to the other experimenter who rewarded it with a piece of fish. If the water-filled ring was chosen it was pulled off the seal's snout, and both rings removed from the water, at which time the seal was given a 30-s rest period as 'punishment'. At least 20 trials were run in each session, and the position of the correct ring (left as opposed to right) was varied at random. After seven sessions run in the dark, the training was continued in daylight as the rings were visually identical. When the seal learned the discrimination, the air-filled ring was ballasted at 101 g and filled with water, and five additional sessions were run. Vocalizations were monitored during all sessions with the Sony recorder, and on three occasions with the Store 4.

During the first phase of the study, when the seal was required to find one ring in the dark, the animal returned it to the experimenter in, on average, 34 s (s.d. = 50.47), although the time it took to locate the ring was slightly less than this. Single and doublet clicks were emitted throughout each session, and click trains were recorded for ~40% of the trials.

During the first session of discrimination training when the seal had to identify the air-filled ring, the correct ring was chosen on 63% of the trials. This level of performance improved until the seal was able to respond correctly on at least 75% of the trials ($t = 2.34$, $P < 0.05$ for trials 1–13 compared with 14–26), the best discrimination ratio being 0.85. The only time the animal responded at less than 50% was in a few sessions just after we switched to training in daylight (see Fig. 2).

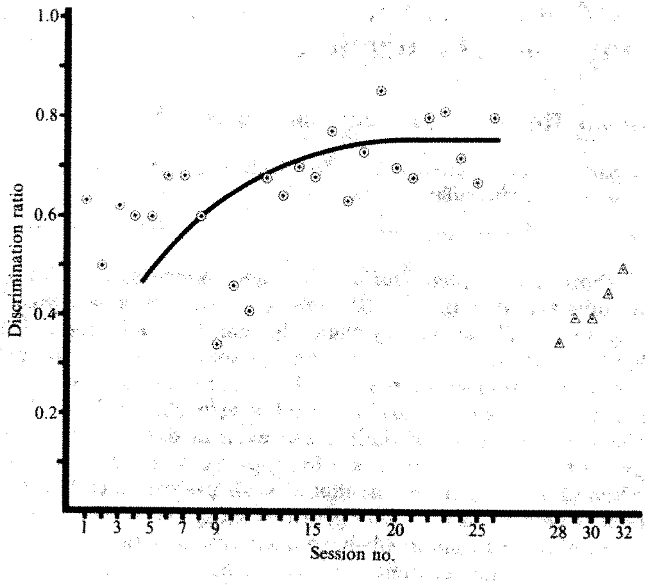

Fig. 2 Performance of the seal during discrimination training (⊕) and after both rings were filled with water (△). The discrimination ratio is the percentage of trials in which the seal chose the correct ring. Training occurred in darkness for the first seven sessions, and thereafter in daylight. The line was fitted by eye.

After 26 training sessions, both rings were filled with water and the seal's performance fell to chance levels ($\bar{x} = 0.42$, s.d. $= 0.06$, $t = 6.82$, $P < 0.05$ for control trials compared with the last five discrimination trials; see Fig. 2).

The only vocalizations that were consistently produced during discrimination training were very faint single or doublet clicks. No click trains such as those emitted during the location task were recorded. There was no evidence of an ultrasonic component to either type of signal.

The following results suggest that the seal was using echolocation: (1) it was able to locate a ring in total darkness; (2) it could discriminate between two objects that were visually identical but which differed in acoustic impedance; (3) the seal produced click vocalizations during the performance of both tasks; and (4) when the same rings were both filled with water, the animal was no longer able to distinguish between them even though it clicked while attempting to retrieve the correct one.

In our pilot study, we were unable to train a harbour seal using the same procedure as that used by Schusterman[7]. We found, as did Scronce and Ridgway[8] and Evans and Haugan[6], that the seal did not click during testing. This was perhaps not surprising as there was no reason to expect the animal to realize the task could be solved by using sonar. We therefore introduced the intermediate step of requiring the animal to first locate one ring in the dark, a situation in which it might be predisposed to using echolocation. For similar reasons we ran the first few sessions of discrimination training in the dark. Throughout the seal's early training sessions, it chose the air-filled ring correctly on about two-thirds of the trials, and only scored <0.50 after we switched to daylight testing. It is tempting to speculate that in the dark when the visual similarity of the rings was not apparent, the seal favoured the air-filled one because it was most salient, returning the loudest echo. However, the discrimination ratios in the seven sessions in the dark and for the first seven in daylight are not statistically different ($t = 0.79$, $P > 0.05$), and it is therefore impossible to determine whether the change in the seal's behaviour was a function of the rings being visible or a reflection of performance instability during early training. Similarly, the increase in the discrimination ratio from 0.35 to 0.50 over the sessions when the seal was presented with two water-filled rings is not statistically significant ($x^2 = 1.32$; $P > 0.05$).

The seal seemed to find the discrimination task difficult; perhaps its sonar system is not sophisticated enough to easily make distinctions like the one we devised. Most proficient echolocators operate primarily in the ultrasonic range as the higher the carrier frequency and/or pulse repetition rate, the better the resolution of the system. Certainly, an echolocator having a low frequency signal would be at a disadvantage in an enclosed tank in which reverberant surfaces are close, and ambient noise high. Quiet individual or doublet clicks emitted after perceptible delays might have been the seal's solution to the problems of reverberation, especially during discrimination training when the rings were close to the tank wall.

Although our experiment provides evidence of echolocation, a study of this type cannot eliminate unequivocally the possibility that some cue of which we were unaware, may have somehow assisted the seal. Norris[3] cautioned that the only way to unequivocally demonstrate echolocation is by blocking the animal's sound reception or emission during discrimination performances. To date, no marine mammal has willingly participated in such a procedure and as Norris goes on to admit, the general acceptance of dolphin sonar abilities rests on "less than perfect experiments". If some method of performing the critical test could be devised which would ensure that the animal was not disrupted in a general way, all doubts about echolocation in pinnipeds could be allayed once and for all.

We thank Linda Gaborko and John Lawson for assistance and advice; Dr Adam Zielinski and Dwight Howse of Memorial University's Engineering faculty for their time, acoustical equipment and expertise; C-CORE for the use of their ultrasonic instruments; and Bora Merdsoy for his advice in the writing of the manuscript. This study was supported by NSERC research grant A6364 (D.R.) and is Marine Sciences Research Laboratory contribution 490.

Research on plant virus vectors has shown that almost all types of organisms feeding on or parasitizing infected plants, including sucking and biting insects, mites, nematodes and chytrid fungi, can act as specific vectors. Surprisingly, however, natural vectors have not been found for some of the most infectious of the plant viruses such as tomato bushy stunt virus (TBSV) and tobacco mosaic virus (TMV). Here we report that when purified TBSV was consumed by human volunteers, it subsequently occurred in their faeces and could be detected by mechanical inoculation of faecal extracts to the leaves of an indicator plant (*Chenopodium quinoa*) in which the virus causes countable, discrete lesions. Thus, the virus remained stable on passage through the alimentary tract. The significance of man as a carrier, able to disseminate the virus widely within the environment, is discussed in relation to the epidemiology of the disease. To our knowledge, this is the first demonstration of an 'alimentary-resistant' plant virus.

TBSV was first isolated[1] from tomato (*Lycopersicon esculentum*) crops in Ireland in 1935 and was later found in tomato crops in England[2]. The virus occurs in nature as a number of different pathogenic but serologically-related strains infecting a variety of crops and other plant species[3] including tomato, pepper, globe artichoke, cherry, hop, grapevine, *Pelargonium* and *Petunia*. Recently, it has caused economically important tomato diseases in Morocco[4] and Tunisia (C. Cherif, personal communication) because diseased plants are stunted and the 'mottled' fruit is unacceptable for export. The distribution of TBSV includes western and central Europe, North Africa, Argentina, Canada and Mexico.

TBSV is a single-stranded RNA-containing virus with isometric particles ~30 nm in diameter. In some experimental hosts (for example, *Nicotiana clevelandii*) it may reach a concentration of ~200 mg per kg of infected leaf. It is readily transmissible by mechanical inoculation and infective leaf

Table 1 Virus recovery from faeces of three volunteers 1–5 days after ingesting TBSV

Treatment	Volunteer	Dilution of sample	Infectivity* of faecal samples on day: 0†	1	2	3	4	5
TBSV in distilled water	T.F.	0	0	8	5	0	0	0
		1/10	0	5	2	0	0	0
	J.F.	0	0	>100	28	3	1	0
		1/10	0	92	16	2	1	0
	J.G.	0	0	>100	19	32	0	0
		1/10	0	>100	10	23	0	0
Distilled water	M.J. E.B. A.C.	0	0	0	0	0	0	0
		1/10	0	0	0	0	0	0

Three volunteers consumed 10 mg purified TBSV in 50 ml distilled water and three volunteers (controls) received water alone. TBSV was purified from systemically infected *N. clevelandii* leaves by *n*-butanol (8.5% v/v) clarification of leaf homogenates in 0.5 M potassium phosphate buffer (*p*H 7.5) followed by differential centrifugation and density gradient centrifugation on 10–40% (w/v) sucrose columns in 0.01 M phosphate buffer (*p*H 7.5). Virus zones containing TBSV were removed, diluted in distilled water and ultracentrifuged. Virus pellets were resuspended in distilled water and stored at −18 °C. Faeces were stored frozen. Samples (2–3 g) were homogenized in 0.05 M phosphate buffer *p*H 7.2 containing 200 μg ml^{-1} penicillin, 200 μg ml^{-1} streptomycin and 10 μg ml^{-1} amphotericin in sodium deoxycholate (Fungizone). After centrifugation at 5,000*g* for 15 min to remove solids, the supernatant was centrifuged for 30 min at 100,000*g*. Faecal pellets were resuspended for 4 h in 1.0 ml 0.005 M phosphate buffer *p*H 7.5 (dilution 0) and aliquots diluted 1/10 in the same buffer. Samples (coded) were manually inoculated to carborundum-dusted *C. quinoa* leaves. Resultant TBSV lesions were counted 5 days after inoculation and recorded before the code was known.

* Mean no. of TBSV lesions in four *C. quinoa* leaves.

† Virus was consumed a few hours after the first collection of faecal samples on day 0.

extracts retain infectivity after freezing for several years[5]. The thermal inactivation point is between 80 and 90 °C.

TBSV is soil-borne[6] and, although most other soil-borne viruses have nematode or fungus vectors, no vector of TBSV is known at present[3,7]. Studies, begun in 1980, on the occurrence of plant viruses in English rivers[8] have isolated TBSV from the rivers Thames and Cam, from tributaries of the rivers Avon (Warwickshire) and Trent and also from Lake Esthwaite (Cumbria). Present investigations on the origin of TBSV in rivers have demonstrated its occurrence in consignments of symptomless tomatoes imported from Morocco to Birmingham in 1982 and in tomato plants growing extraneously in sludge at sewage works in Warwickshire and Leicestershire[9]. In an attempt to explain its presence in river water and in the tomato plants growing in sludge, we have postulated that the virus remained infective after human consumption of TBSV-infected tomato fruit and that it was then transported to rivers after treatment of infective faeces at sewage works.

An *in vitro* test showed that the infectivity of TBSV (isoelectric point, *p*H 4.1) was retained after storage at *p*H 3.0, a value similar to that of many samples of gastric juice. An homogenate of TBSV-infected *N. clevelandii* leaves in distilled water (1 g per 2 ml) was clarified by centrifugation at 5,000*g* for 10 min and aliquots of the infective supernatant fluid adjusted with 10% HCl to *p*H 3.0, 3.5 and 4.0. An unadjusted aliquot (*p*H 6.5) was used as a control. After incubation for 1 or 3 h at 25 °C, the samples were neutralized (*p*H 7.0) with NaOH, stored at 4 °C for 5–6 h to allow virus resuspension and 10-fold dilutions of the samples assayed for infectivity by mechanical inoculation of *C. quinoa* leaves. Based on the numbers of lesions formed in the leaves after 5 days, no differences in the infectivity end points were found between the acid-treated and control samples.

The *in vivo* experiment was as follows. Six adult volunteers were randomly divided into two groups. Each of three volunteers (T.F., J.F. and J.G.) consumed 10 mg of purified TBSV in 50 ml distilled water and three volunteers (M.J., E.B. and A.C.) received water alone. Each volunteer consented not to eat tomatoes for 7 days before the start of the experiment. Faeces was collected from each volunteer 1 day before and daily for 5 days after consuming the test liquids. After storage at −18 °C, the faecal collections were sampled and assayed for TBSV infectivity (Table 1). TBSV was detected in faeces of each of the volunteers receiving virus but not in those from the control volunteers. For individuals receiving virus, the infectivity was similar and high in faecal extracts of two volunteers (J.F. and J.G.) but it was relatively low in the case of the third volunteer (T.F.). The reason for this is unknown, but may be due to errors in faecal sampling.

The result demonstrates the remarkable stability of TBSV in that it retained its infectivity after ingestion and successive exposure at 37 °C to the enzymes of the alimentary tract, bile salts and wide fluctuations in *p*H (~3.0–8.8).

Retrospectively, the chances of plant viruses surviving passage through the alimentary tract have usually been considered remote. With most plant viruses this may be true as with those sometimes consumed in infected raw vegetables including lettuce mosaic, celery mosaic, carrot mottle and, in brassicas, the cauliflower and turnip mosaic viruses. This is because, in infective plant tissue extracts, these viruses would be rapidly inactivated at 25 °C in solutions of *p*H 4.0–5.0. However, not all enteric pathogens need to be acid-stable—for example, *Vibrio cholerae* is not acid-stable—thus other agents present in a quantity of food could survive transit through the stomach. The more stable plant viruses such as the tomato and pepper strains of TMV may be sufficiently intrinsically stable to resist digestion, and experiments to test their possible 'alimentary resistance' will now be done. Similarly, the resistance of viroids[10], for example, cucumber pale fruit and potato spindle tuber viroids, needs to be determined; although readily hydrolysed by pancreatic RNase *in vitro* in weak salt solutions (0.005 M phosphate buffer, *p*H 7.5), these are more resistant to the enzyme in solutions of higher molarity.

The results presented here suggest that man is a potential carrier of TBSV if he has consumed infected produce. The possibility exists that TBSV could enter rivers after sewage treatment of infective faeces but whether the virus is stable after this treatment is unknown, although its presence in tomato plants growing extraneously in primary settlement beds has been confirmed. Further dissemination might also occur by irrigation of susceptible crops with infective river water. Whether human factors (infective faeces) contribute to the incidence of TBSV in Moroccan[4] and Tunisian (C. Cherif, personal communication) tomato crops merits further study. We shall now examine other plant viruses having no known vectors for their 'alimentary resistance', as man and other migratory animals may prove to be important carriers of these viruses also.

We thank Mr M. Knott for tomato samples, and the Severn and Trent River Authority for access to the sewage engineering sites. We also thank the Ethical and Research Committee of the East Birmingham Hospital whose permission made this experiment possible.

Specific inhibition of the morphogenesis of *Trypanosoma cruzi* by a monoclonal antibody

Alan Sher

Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, Bethesda, Maryland 20205, USA

David Snary

Department of Molecular Biology, Wellcome Research Laboratories, Beckenham, Kent BR3 3BS, UK

***Trypanosoma cruzi*, the causative agent of Chagas' disease, is transmitted primarily by blood-sucking reduviid bugs. The insects themselves are infected by ingesting trypomastigotes with the blood of infected mammals. On ingestion by the vector, the parasites convert to epimastigotes which multiply within the lumen of the crop and midgut. In the hindgut and rectum of the reduviid, the epimastigotes transform into non-dividing metacyclic trypomastigotes which can, when passed with the faeces, infect the vertebrate host[1]. Lectins capable of binding *T. cruzi* have been isolated from different regions of the vector's intestinal tract[2,3]. It has been proposed that the interaction of these lectins with the surface membrane of the parasite regulates the morphogenesis of *T. cruzi* in the gut of the vector[2,3]. In the present study we describe the inhibition of epimastigote to trypomastigote differentiation *in vitro* by a monoclonal antibody specific for a 72,000 molecular weight cell-surface glycoprotein of *T. cruzi* and propose that this molecule may be a receptor controlling parasite differentiation in the vector.**

The transformation of epimastigotes into trypomastigotes was studied in an *in vitro* assay which is described in detail elsewhere[4]. In this system, log phase epimastigotes (Tulahuen strain) cultured in liver infusion tryptose (LIT) medium are programmed for differentiation by inoculation into Millipore filter (0.45 μm) chambers which are then implanted subcutaneously in mice. When recovered 7 h after *in vivo* implantation these organisms are still in the epimastigote stage as judged by morphological criteria as well as their sensitivity to complement lysis and binding of specific lectins[4]. Nevertheless, on transfer to Eagle's minimal essential medium (EMEM) and incubation for 17 h at 37 °C in a 5% CO_2 atmosphere, 60–80% of the parasites transform into morphologically distinct trypomastigotes. This *in vitro* transformation is not observed when epimastigotes are cultured in the same conditions in the absence of prior *in vivo* programming[4].

Table 1 Monoclonal antibody reagents tested

Hybridoma	Ig class	Reciprocal IFA titre	Reciprocal agglutination titre
WIC 59.4	IgM	10^5	10^4
WIC 14.19	IgG1	10^3	10^2
WIC 29.19	IgG1	$>10^5$	$>10^5$
WIC 29.82	IgG3	10^2	$<10^1$
WIC 53.1	IgG2a	10^2	10^1
WIC 29.26	IgG2a	$>10^5$	10^3
	Fab	$>10^5$	$<10^1$

Indirect fluorescent antibody (IFA) titres were determined by adding log dilutions of Protein A-purified monoclonal antibodies or papain-digested Fab fragments (starting concentration of approximately 5 mg ml^{-1} to epimastigotes collected from LIT medium. The parasites were then incubated for 1 h at 37 °C, washed twice and incubated for an additional 30 min at room temperature with a 1/40 dilution of fluorescein-conjugated rabbit anit-mouse heavy and light chains (Cappel). After further washing, the parasites were examined in a fluorescence microscope. Direct agglutination of parasites was assayed by adding log dilutions of purified monoclonal antibody (or Fab fragments) to LIT derived epimastigotes (5×10^6 per ml) in EMEM plus 1% bovine serum albumin in round-bottom microtitre trays. After 1 h at 37 °C, agglutination of the parasites was scored by examination with an inverted microscope.

A series of six monoclonal antibodies reactive with the epimastigote surface and an epimastigote binding lectin, wheat germ agglutinin (WGA), were tested for their ability either to inhibit or promote epimastigote differentiation in the *in vitro* assay. The monoclonal antibodies were produced by fusing P3-NS1/1-AG-4-1 myeloma cells with spleen cells from BALB/c mice immunized with glutaraldehyde fixed epimastigotes as described previously[5]. With the exception of WIC 59.4, an IgM antibody, each of the monoclonal antibodies was purified from ascites by affinity chromatography on Protein A–Sepharose[6]. The purified antibodies (unpurified ascites in the case of WIC 59.4) were found to have indirect fluorescent antibody titres ranging between 10^2 and $>10^5$ and to have parasite agglutination titres ranging between $<10^1$ and $>10^5$ (Table 1). The epimastigote binding lectin, WGA, agglutinated the parasites at concentrations as low as 8 μg ml^{-1}.

When tested in the *in vitro* differentiation assay, only one of the reagents, an IgG2a monoclonal antibody WIC 29.26, significantly influenced the differentiation of epimastigotes into trypomastigotes. As shown in Fig. 1, the purified antibody significantly inhibited parasite transformation at dilutions as high as 10^5 which is equivalent to an IgG to parasite ratio of 5 ng per 10^6 organisms. No inhibitory activity was observed with the five other monoclonal antibodies at any of the concentrations tested. The effect of a representative negative antibody (WIC 29.19) with high anti-epimastigote binding activity is shown in Fig. 1. Similarly, no inhibitiion of transformation was observed with WGA even at concentrations as high as 250 μg ml^{-1} (data not shown).

A trivial explanation of the inhibitory effect of WIC 29.26 on parasite transformation is that the antibody is trypanocidal or trypanostatic. Arguing against this hypothesis is the observation that incubation with WIC 29.26 causes no reduction in

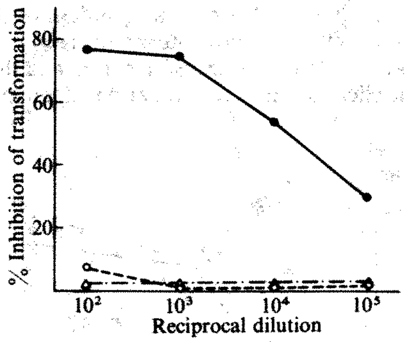

Fig. 1 Inhibition of epimastigote to trypomastigote transformation by monoclonal antibody WIC 29.26. Epimastigotes (Tulahuen strain) were collected from log phase cultures in LIT medium containing 10% fetal calf serum, washed in LIT, and inoculated into Millipore chambers which were then implanted subcutaneously into C57BL/6J mice. Seven hours later the parasites were recovered from the chambers, washed in EMEM and resuspended in EMEM to a final concentration of approximately 10^7 epimastigotes per ml. Aliquots (45 μl) of the parasite suspension were then cultured together with 5 μl of monoclonal antibody or Fab preparation in EMEM for 17 h at 37 °C in a humidified atmosphere of 5% CO_2. The contents of duplicate microwells were then smeared, Giemsa stained and the percentage of mature trypomastigotes plus partially transformed trypomastigotes determined by morphological examination[4]. In the representative experiment shown, 76% of the parasites cultured in the absence of inhibitor differentiated into trypomastigotes. The effect of the following Protein A–Sepharose-purified antibody preparations (used at an initial concentration of 5 mg ml^{-1}) is shown: WIC 29.26 IgG2a (●), WIC 29.26 Fab (△), WIC 29.19 IgG1 (○).

0028–0836/82/500639—02$01.00

epimastigote motility or in the number of total parasites recovered at the end of the 17-h assay period and that upon transfer to LIT medium after incubation in WIC 29.26 antibody parasites display subsequent growth kinetics indistinguishable from those exhibited by programmed epimastigotes or programmed epimastigotes pre-incubated with a control monoclonal antibody (WIC 29.19) (Fig. 2). Similarly, during the 17-h incubation with WIC 29.26 antibody, no inhibition of total protein synthesis (as measured by ^{75}Se-selenomethionine incorporation) is observed nor do major differences appear in the pattern of labelled proteins (as analysed by SDS–polyacrylamide gel electrophoresis) when parasites incubated in the presence or absence of WIC 29.26 antibody are compared (data not shown).

In order to investigate further the mechanism by which WIC 29.26 inhibits trypomastigote differentiation, monovalent Fab fragments were prepared from the purified antibody by papain digestion. Although the Fab preparation displayed the same indirect fluorescent antibody titre for epimastigotes as the bivalent WIC 29.26 (Table 1) it failed to inhibit transformation in the *in vitro* assay (Fig. 1).

The above findings demonstrate that monoclonal antibody WIC 29.26 potently and specifically inhibits the transformation of epimastigotes into trypomastigotes. The epimastigote surface antigen recognized by WIC 29.26 antibody has already been identified[5]. The antigenic determinant resides on the carbohydrate portion of a 72,000 molecular weight glycoprotein[5] which is present on the surface of epimastigotes and metacyclic trypomastigotes but absent on bloodstream trypomastigotes and amastigotes (D.S., unpublished data). Although the exact role of the 72,000 molecular weight glycoprotein in parasite differentiation remains to be elucidated, the failure of WIC 29.26 monovalent Fab fragments to inhibit transformation (Fig. 1) suggests that cross-linking of the molecule is essential for the biological effect.

Our data predict the occurrence of a substance in the gut of the invertebrate host with a binding specificity and biological activity similar to the WIC 29.26 monoclonal antibody. Indeed, as mentioned earlier, lectins which react specifically with different morphological stages of *T. cruzi* have already been identified in different portions of the reduviid intestinal tract[2,3]. If present in the lining of the crop and midgut of the vector, a lectin reactive with the carbohydrate moiety recognized by WIC 29.26 antibody, could inhibit transformation and thereby regulate the multiplication and accumulation of epimastigotes in this anatomical site.

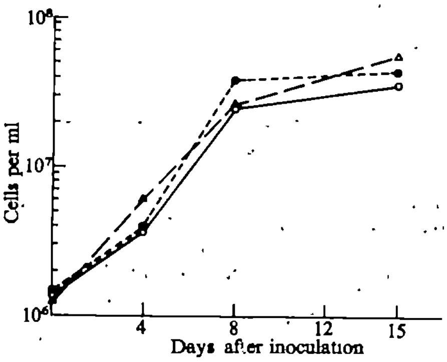

Fig. 2 Incubation with WIC 29.26 antibody has no effect on parasite viability or subsequent growth in culture. *In vivo* programmed epimastigotes incubated in EMEM for 17 h in the absence of inhibitors (○) or in the presence of a 1/1,000 dilution of either WIC 29.26 (△) or WIC 29.19 (●) monoclonal antibody were diluted 1:10 in LIT medium plus 10% fetal calf serum and the growth of the parasites assayed by haemacytometer counts. The results are the mean of assays on duplicate cultures. The absence of a significant lag in the growth of control, programmed cultures probably reflects rapid transformation of non-dividing trypomastigotes into epimastigotes during the first 4 days of culture.

We thank Sara Hieny for technical assistance and Louis V. Kirchhoff for helpful discussions.

Alteration in the penicillin-binding profile of *Bacillus megaterium* during sporulation

John A. Todd & David J. Ellar

Department of Biochemistry, University of Cambridge,
Tennis Court Road, Cambridge CB2 1QW, UK

The development of convenient methodology to study penicillin-sensitive enzymes (PSEs) as penicillin-binding proteins (PBPs)[1,2] has revealed their roles in bacterial cell shape determination, particularly in the Gram-negative rod *Escherichia coli*[3–6]. By analysing PBPs during the life cycle of *Bacillus megaterium* KM we report here the first data suggesting specific roles for these proteins in the morphogenesis of a Gram-positive rod. During the transition from the vegetative rod to the spherical/ellipsoidal-shaped dormant spore, novel PBPs are synthesized and existing ones are proteolytically modified. The differentiation of the dormant spore PBP profile back to that of the vegetative cell during germination, follows a defined sequence clearly correlated to specific changes in shape, culminating in a highly synchronous vegetative cell division.

The sporulating bacteria offer one of the most attractive prokaryotic systems to explore the cellular role of PBPs. In appropriate growth conditions, these bacteria can be induced to undergo a limited number of central septations in a synchronous manner (vegetative growth) followed by one final synchronous septation which differs from all previous septations by being asymmetrically positioned close to one cell pole[7]. Following this unequal partitioning of the cell which is unique to sporulating cells, the membranes comprising this asymmetrical septum continue to proliferate towards the nearest cell pole with the result that a separate spherical/ellipsoidal compartment (forespore) containing at least one complete genome is created within the parent cell (mother cell)[8]. By the nature of its formation, the forespore is enclosed by two membranes of opposite polarity[9]. During the next 12 h, in a series of well defined morphological and biochemical changes programmed by transcription of spore-specific genes, this forespore is converted into a mature spore[10]. The overall sporulation process is divisible into seven distinct stages (0–VI)[11,12]. Stage II describes the asymmetric septation event and stage III denotes the first appearance of the discrete forespore. Of particular interest to the question of cell shape determination is the fact that within the cylindrical mother cell, a spherical/ellipsoidal layer of peptidoglycan (spore cortex) is synthesized between the two bounding membranes of the forespore during stages III and IV[13–16]. In addition to its altered shape, the chemistry of this cortex peptidoglycan is radically different from that of the parent cell[14,17]. Thus, the sporulating cell not only provides an opportunity to investigate the switch from symmetrical to asymmetrical division and hence to probe polarity mechanisms, but also to study the chemical and enzymatic basis of a transition from cylindrical to spherical/ellipsoidal shape. Interestingly,

0028–0836/82/500640—04$01 00

these transitions can also be investigated in reverse as dormant spores can be triggered to germinate and outgrow synchronously[8,17,18]. Approximately 180 min after germination triggering, the peptidoglycan composition has reverted to that of a typical vegetative cell, the cells have regained their cylindrical shape and the population undergoes its first synchronous central septation[16,18,19].

We analysed PBPs in membranes isolated from vegetative cells (Fig. 1*a*), mother cells (Fig. 2) and forespores during sporulation (Fig. 1*b–e*), and from dormant (Fig. 1*f*) and germinated spores (Fig. 1*g-h*). Vegetative membranes of this sporogenic *B. megaterium* KM contained five PBPs identical both in their mobilities on SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and in their affinities for benzylpenicillin, to PBPs 1–5 of an asporogenic *B. megaterium* KM strain[20]. In addition, four previously undetected PBPs were identified and designated PBPs 3a, 3b (Fig. 1*a*), 3c and 3d (Fig. 1*d*). The apparent molecular weights (MWs), affinities for benzylpenicillin and specific amounts of the PBPs in vegetative and forespore membranes of *B. megaterium* KM, are shown in Table 1.

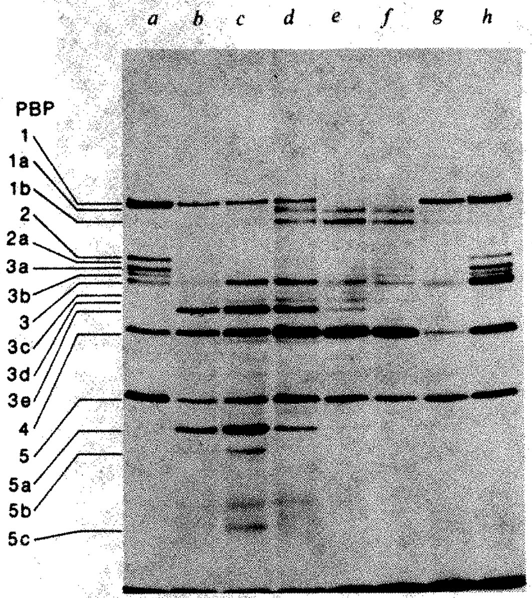

Fig. 1 Fluorogram of PBPs of membranes isolated from vegetative cells, forespores and dormant and germinated spores of *B. megaterium* KM. The conditions for growth and sporulation were as described previously[27,28]. Intact cells (exponentially growing vegetative cells, isolated forespores, dormant and germinated spores) were disrupted by homogenization with glass beads in 0.05 M Tris-HCl *p*H 7.5 buffer, containing 2 mM phenylmethanesulphonylfluoride (PMSF)[29]. Cell walls or integuments were sedimented (27,000 *g* for 3 min) and integument fractions[29] from stage V and VI forespores and dormant spores were washed four times by resuspension in 0.05 M Tris-HCl *p*H 7.5, 5 mM $MgCl_2$. The integument fractions isolated from developing and mature spores contained the outer forespore/spore membrane trapped between the proteinaceous spore coats and the cortex from stage V onwards[30–32]. The supernatant fraction was centrifuged twice (27,000*g* for 3 min) and the final supernatant was further centrifuged (105,000*g* for 60 min) to sediment membranes, which were washed twice by repeated centrifugation and resuspended in 0.05 M Tris-HCl *p*H 7.5, 5 mM $MgCl_2$ buffer. In the preparation of membranes from the sporulation stages, forespores were released after the lysozyme digestion step and the forespores and mother cell membranes isolated by differential centrifugation[28]. The temperature of all preparations was rigorously maintained below 4 °C. Freshly prepared dormant spores were germinated as described by Wilkinson *et al.*[33] in a modified sporulation medium (CCY medium) at a cell density of 0.5 mg dry weight ml^{-1}. The medium contained glutamine (50 mg l^{-1}), acid casein hydrolysate (2.5 g l^{-1}), enzymatic casein hydrolysate (2.5 g l^{-1}), yeast extract (1.0 g l^{-1}), glycerol. (1.5 g l^{-1}) plus germinants (10 mM L-alanine and 5 mM inosine). Salts, at the normal concentrations of CCY medium[27], were added 45 min after the time of transfer of spores to the medium (t_{45}). Germination, outgrowth, elongation and the first vegetative cell division were monitored by phase contrast microscopy and membranes were prepared from cells at t_{85} (elongation) and t_{200} (cell division). Membranes, at 5–10 mg protein per ml, were incubated at 37 °C for 10 min with ^3H-benzylpenicillin (25 μg ml^{-1}; 31Ci $mmol^{-1}$) in 0.05 M Tris-HCl *p*H 7.5, 5 mM $MgCl_2$ buffer. After reaction, samples were supplemented with a 1,000-fold excess of nonradioactive benzylpenicillin and an equal volume of SDS sample buffer (0.05M Tris-HCl, *p*H 7.5, 2% (w/v) SDS, 0.05 M dithiothreitol, 4 mM PMSF, 2 mM EDTA, 20% (w/v) glycerol, 0.005% (w/v) bromophenol blue), heated at 100 °C for 3 min, and subjected to 10% SDS-PAGE as described previously[29]. Equal aliquots of protein, estimated by the method of Lowry *et al.*[34], were loaded on each track. PBPs were detected by fluorography[35], using pre-flashed Fuji X-ray film. *a*, Vegetative plasma membranes; *b*, inner (ifm) and outer (ofm) forespore membranes of stage III; *c*, stage IV, ifm and ofm; *d*, stage V, ifm; *e*, stage VI, ifm; *f*, dormant spore inner membrane; *g*, *h*, plasma membranes of germinated spores at t_{85} and t_{200}, respectively.

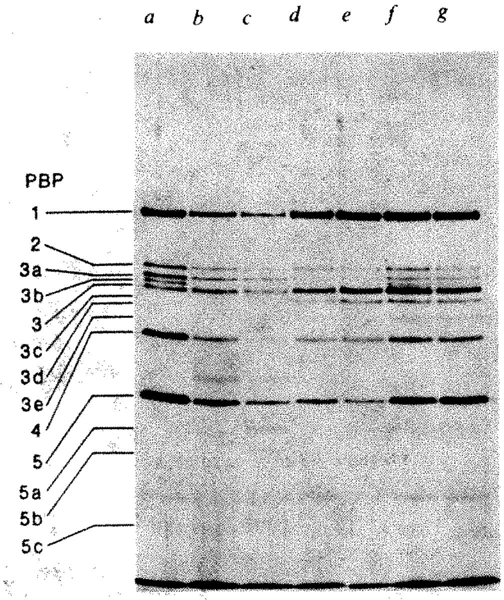

Fig. 2 Fluorogram of PBPs in the plasma membranes isolated from vegetative cells (*a*); sporulating cells at stage I (*b*) and stage II (*c*); and mother cells at stage III (*d*), stage IV (*e*), stage V (*f*) and stage VI (*g*). Mother cell plasma membranes, separated from the forespore membranes by differential centrifugation (see Fig. 1), and total cell membranes were prepared and assayed for PBPs as described in Fig. 1 legend.

During sporulation and, significantly, during cortex synthesis, dramatic changes in the number and level of PBPs were observed in the forespore membranes compared with the plasma membranes isolated from the corresponding mother cell (compare Fig. 1 *b–e* and Fig. 2*d–g*). Novel PBPs were designated PBP 1a (doublet), 1b, 2a, 3e, 5a, 5b and 5c (Figs 1, 2). PBPs 5b [MW ~ 41,000 (41 K)] and 5c (MW ~ 39 K) were not characterized further. These changes in PBPs are almost certainly sporulation-specific and not a response to nutrient limitation, as an asporogenic *B. megaterium* KM strain[20] grown in sporulation medium for the same time as an equivalent stage IV culture, did not show any significant changes in PBPs (data not shown).

Peptide maps of PBPs 1a and 1b, obtained by partial proteolysis with staphylococcal V8 protease, were identical to that of PBP 1 (Fig. 3), suggesting a common structural identity. Similarly, on appropriately exposed fluorographs it is apparent that PBP 3c may be related to PBP 1, PBP 2a to 2 and PBP 3b to 3a (data not shown). In contrast, PBPs 3e and 5a have unique peptide profiles suggesting that these proteins may be both novel and sporulation-specific as opposed to proteolytic fragments derived from higher molecular weight PBPs. Furthermore, limited proteolysis of PBP 5a with α-chymotrypsin (Fig. 3*c*) and papain (Fig. 3*d*) produced peptides distinct from those of PBP 5 and PBPs 3e, 1, 3 and 4 (Fig. 3*c*, *d*).

In preliminary experiments (J.T. and D.E., in preparation), PBP 5a showed D-alanine carboxypeptidase activity with a *p*H optimum similar to the vegetative cell membrane carboxypeptidase, which is attributed to PBP 5 (ref. 20). *p*-Chloromercuribenzoate (PCMB) inhibits the binding of penicillin only to PBPs 5, 5a and 3e (data not shown). PBP 3e was thus clearly distinguished from higher molecular weight PBPs by virtue of this sensitivity to PCMB, its lower affinity for benzylpenicillin (Table 1) and a completely distinct peptide profile (Fig. 3). It is likely, therefore, that PBP 3e represents a unique PSE active in the synthesis of spore-specific

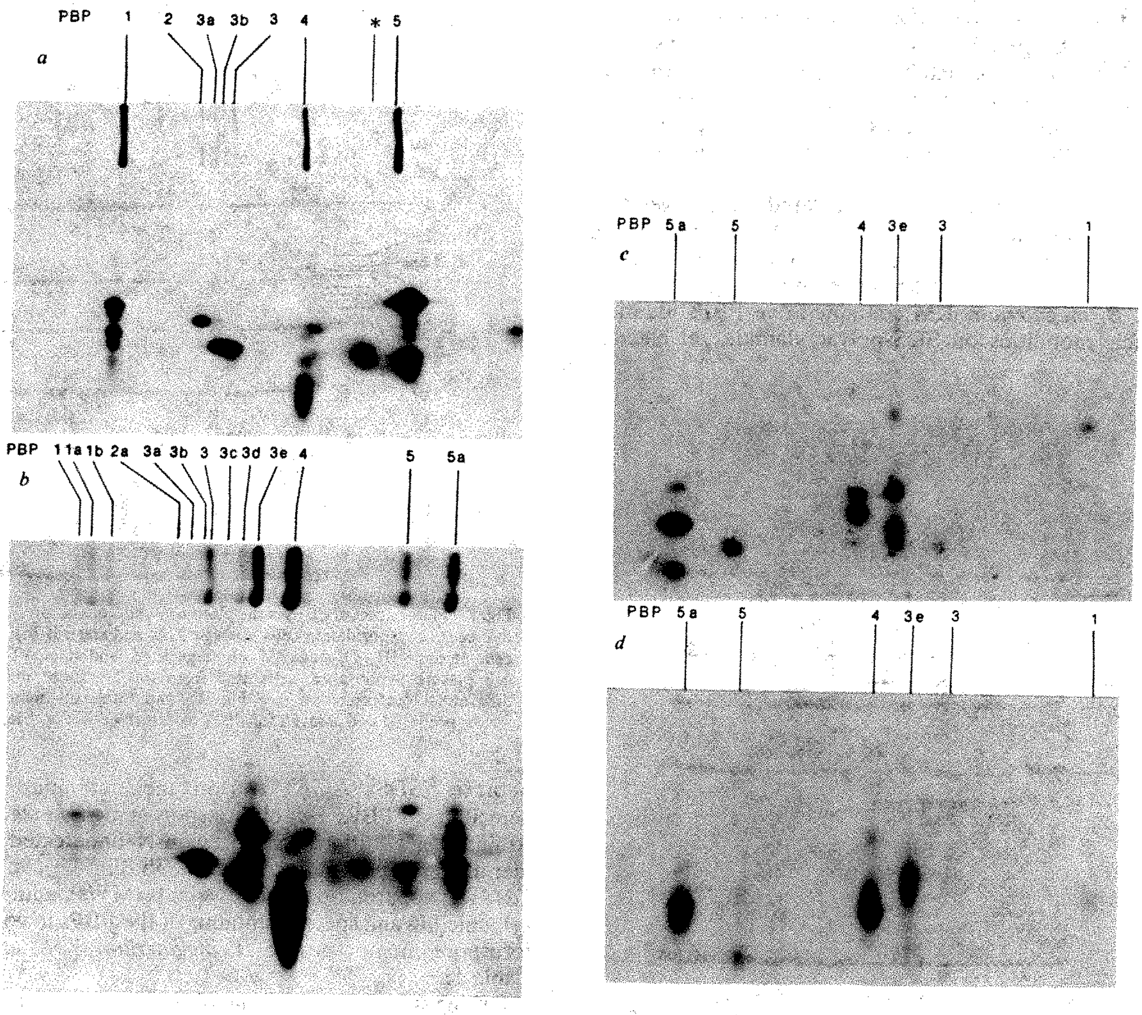

Fig. 3 Fluorograms of ^{3}H-benzylpenicillin-labelled peptides (obtained by partial proteolysis of PBPs with 100 μg of *Staphylococcus aureus* V8 protease) from vegetative plasma membranes (*a*) and stage VI forespore inner membranes (*b*). (*c*) and (*d*) show the peptide maps of PBPs 1, 3, 3e, 4, 5 and 5a obtained by partial proteolysis of stage IV forespore inner membranes with 125 μg α-chymotrypsin and 500 μg papain, respectively. The method used was based on that of Cleveland *et al.*[36], as modified by G. Stewart and D.J.E.[38]. Membrane protein (75–100 μg) was reacted with ^{3}H-benzylpenicillin (50 μg ml^{-1}) and separated by 10% SDS-PAGE as described in Fig. 1 legend. An 18% acrylamide gel was prepared with a 5-cm 6% acrylamide stacking gel. A 2-cm space was left above the stacking gel to accommodate the one-dimensional track which was overlayed with 0.5 ml of stacking gel containing the protease. Electrophoresis was as described previously[29] except that the current was switched off for 30 min just before the bromophenol blue entered the 18% gel. The gels were prepared for fluorography with sodium salicylate, as described by Chamberlain[37]. Duplicate tracks from the first dimension gel were fluorographed and shown in the figure as markers for each PBP in the peptide map. * The labelled peptide in this position is a result of nonspecific penicillin binding to a major membrane protein.

peptidoglycan. The second sporulation-specific protein, PBP 5a, may regulate the degree of cross-linkage (10-fold lower in spore peptidoglycan than in vegetative peptidoglycan[14,21]) and/or provide a suitable tetrapeptide substrate for the transpeptidase synthesizing spherical/ellipsoidal peptidoglycan at stage IV. PBP 5a may thus be analogous to PBP 5 in rod-shaped *E. coli* which, when overproduced, results in spherical growth[22].

In addition to the characteristic differences observed at stage V between the inner forespore membrane (ifm) (Fig. 1*d*) and the mother cell membrane (Fig. 1*f*), the outer forespore membrane (ofm) at this time is devoid of PBPs 1, 1a, 1b, 2, 2a, and 3a–3d and contains only 30% of the total forespore penicillin-binding capacity (data not shown). This suggests that the forespore compartment is directing the synthesis of novel PBPs into the inner forespore membrane and may indicate a role for the forespore cytoplasm and inner membrane in cortex assembly. A similar role was previously suggested by Frehel and Ryter[15] on the basis of their autoradiographic studies.

The re-establishment of the vegetative rod shape by a combination of swelling (t_0–t_{45}) and elongation (t_{45} onwards) during germination, was accompanied by a return to a PBP profile resembling that of the vegetative cell. This was achieved by a specific decrease in PBP 4 from t_{60} and the reappearance of PBP 1 from t_{45} as demonstrated by the PBP profile of cells at t_{85} (Fig. 1*g*). These data suggest that PBP 4 functions specifically in the synthesis of spherical peptidoglycan during t_0–t_{60} while PBP 1 may be concerned with polymer synthesis during elongation (a fuller characterization of germination-associated changes in PBPs will be presented elsewhere). The latter proposal is consistent with that of Reynolds *et al.*[23], who have suggested that PBP 1 is the major transpeptidase of *B. megaterium* KM. Hence, the substantial reduction in PBP 1 and the appearance of its proteolytic fragments, PBPs 1a and 1b, during sporulation may indicate a control mechanism that suppresses vegetative cell elongation in the stage III forespore as a prerequisite for the synthesis of spherical/ellipsoidal peptidoglycan. The role specified here for PBP 4 in the synthesis of spherical-shaped peptidoglycan is consistent with the results of Taku *et al.*[24]. They purified a PBP (MW ~ 61 K) from *B. megaterium* 899 having transglycosylase activity *in vitro* but with no demonstrable transpeptidase activity, which probably corresponds to PBP 4 of *B. megaterium* KM. Because PBPs 1a, 1b and 3 of *E. coli* are probably the transpeptidase/transglycosylase enzymes responsible for lateral wall and septum peptidoglycan synthesis respectively[3–6], Taku *et al.*[24] have suggested analogous enzyme activities and roles in cell growth of *B. megaterium* for PBPs 1 and 4.

The present paper provides the first experimental support for the hypothesis that PBPs/PSEs have central and distinct roles in the morphogenesis of Gram-positive rod-shaped bac-

Table 1 PBPs of the membranes from vegetative and sporulating cells and dormant and germinated spores of *B. megaterium* KM

Membranes were prepared from exponentially growing vegetative cells (Exp), stage I and II sporulating cells, stage III, IV, V and VI forespores, dormant (DS) and germinated spores (GS, t_{85} and GS, t_{200}) as described in Fig. 1 legend. Stage III and IV forespore membranes were a mixture of the ofm and ifm; stage V and VI forespore membranes and dormant spore membranes were, respectively, the ifm and spore inner membrane (im) only. The values of the affinities for benzylpenicillin of PBPs 1, 2, 3, 4 and 5 were taken from Chase *et al.*[20]. The affinities of the other PBPs for benzylpenicillin were estimated as described previously[20] (PBP 2a (MW ~ 90 K) has an affinity of 0.1 μg ml^{-1}, data not given). Molecular weights were estimated by the relation of log MW to the R_f of ^{14}C-methylated protein standards (Amersham). PBPs were quantified by estimation of the amount of radioactivity associated with the appropriate gel slice after location by fluorography (see Fig. 1 legend). Gel slices were prepared for liquid scintillation counting by the method of Tishler and Epstein[26]. Slices were solubilized by incubation at 50 °C for 24 h with 0.3 ml (30%/100 vols) of hydrogen peroxide. Determination of radioactivity was as described previously[27]. The number of PBP molecules per 10^{-15} g protein was calculated from the specific activity of the label. – Denotes that the PBP was not detectable after prolonged exposure of the fluorogram and + denotes that the counts associated with the PBP were insufficient to permit quantitation.

teria in a manner analogous to those of *E. coli*[3–6,22,25]. It also establishes PBPs 3e and 5a as unique sporulation-specific membrane-bound enzymes. The differentiation of PBPs during *B. megaterium* KM development should provide an ideal system to study differential gene expression in two separate intracellular compartments of a prokaryote and the mechanisms by which these proteins determine bacterial cell shape.

This work was supported by the Department of Education for Northern Ireland and the SERC. We thank Dr Stapley (Merck, Sharp & Dohme, New Jersey) for the gift of ^{3}H-benzylpenicillin and Drs G. Stewart, C. Harrington and P. Reynolds.

Elucidation by FAB–MS of the structure of a new cardioactive peptide from *Aplysia*

Howard R. Morris, Maria Panico, Andrew Karplus*, Philip E. Lloyd* & Bernhard Riniker*

Department of Biochemistry, Imperial College,
London SW7 2AZ, UK

The nervous system and gut of *Aplysia* and other gastropod molluscs contain several classes of cardioactive peptides[1]. In addition to their excitatory action on the heart, these peptides stimulate contractile activity in the gut[1], and modulate neurally induced contractions of somatic muscles[2]. This report describes the purification and sequence determination by a combination of microprotein chemistry and fast atom bombardment mass spectrometry FAB–MS[3,4] of one of these peptides. The sequenced peptide is a member of the small class of cardioactive peptides and was termed SCP$_B$. A peptide with identical properties to SCP$_B$ has been found in several identified central neurones which innervate the gut[5]. Here we report the structure of SCP$_B$ as a C-terminally blocked peptide

H-Met-Asn-Tyr-Leu-Ala-Phe-Pro-Arg-Met-NH$_2$

Native and synthetic SCP$_B$ have identical actions on molluscan muscle preparations with thresholds at around 10^{-10} M.

---

* Present addresses: Department of Biochemistry, University of Washington, Seattle, Washington 98159, USA (A.K.); Centre for Neurology and Behaviour, College of Physicians and Surgeons, Columbia University, New York, New York 10032, USA (P.E.L.), CIBA-Geigy A. G., Basel, Switzerland (B.R.).

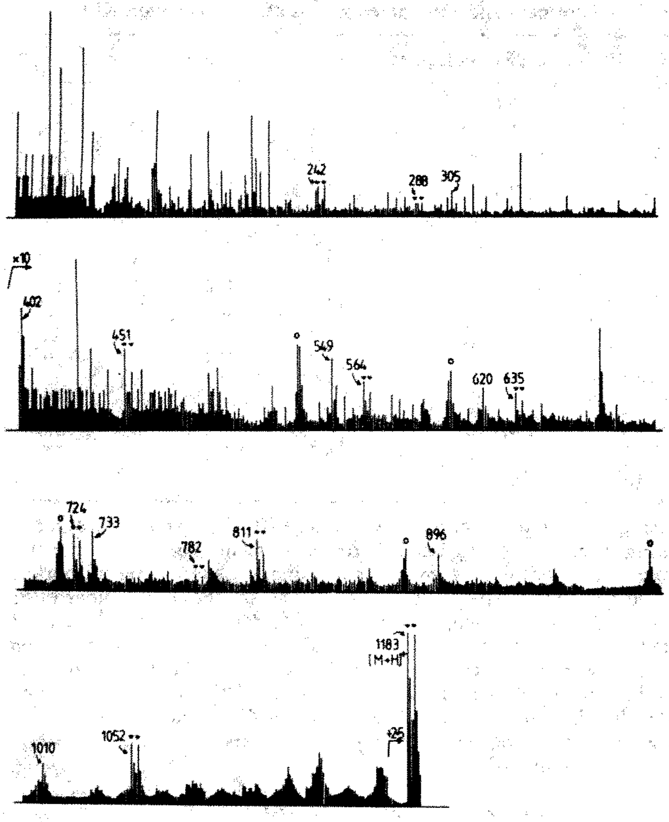

Fig. 1 Fast atom bombardment mass spectrum of the *N*-(1:1 acetyl: d_3-acetyl) derivative of SCP_B(1 μg). Ions arising from the N-terminus appear as 1:1 doublets, three mass units apart. The doublets and C-terminal singlets have been marked for clarity.

The central nervous systems from 2,500 *Aplysia brasiliana* were used as starting material. The homogenization, desalting and gel filtration steps were as previously described[6]. After each step, the active fractions were located by their inotropic action on an isolated snail heart assay[7]. The active fractions were applied to a cation-exchange column of SP-Sephadex (Pharmacia) at *p*H 6.0, and a linear gradient applied from 10 mM NH_4 acetate (*p*H 6.0) to 100 mM NH_4 acetate, 100 mM NH_4OH (*p*H 9.6). The cardioactive material eluted as a single peak which was further purified by HPLC. The sample was taken up in 0.1% trifluoracetic acid (TFA) and applied to a Bondapak C18 column (Waters). A reverse phase gradient was developed from the sample buffer to 0.07% TFA in acetonitrile. Two active peaks termed SCP_A and SCP_B were obtained (evidence from FAB–MS analyses suggests that the peak termed SCP_A contains the oxidized form of SCP_B which may account for its biological activity). Quantitative amino acid analysis suggested that SCP_B was a single peptide species with the following amino acid composition normalizing on Arg = 1:

$$\mathrm{Asx_{1.0}Ser_{0.2}Pro_{0.9}Gly_{0.3}Ala_{1.0}Met_{1.7}}$$
$$\mathrm{Leu_{1.2}Tyr_{0.8}Phe_{0.9}Arg_{1.0}}$$

The recovery from the final purification (1,000 animals) was 15–20%, with a yield of 10 nmol. Thus the original content of SCP_B in each nervous system (animal weight 400 g) was approximately 60 pmol.

After biological experiments and amino acid analyses 6 nmol were available for the mass spectrometric study. Each experiment was therefore restricted to 1.5 nmol (approximately 1 μg of SCP_B per analysis). The first sample was examined directly by FAB–MS as the free peptide, and gave a clear signal at 1,141, indicating a molecular weight for SCP_B of 1,140. This was in approximate agreement with that anticipated from amino acid analysis. Sequence ions in the spectrum were weak and the complexity did not allow an interpretation. A further 1 μg of SCP_B was treated with acetic anyhydride: d_6 acetic anhydride 1:1 v/v in methanol for 1 min at room temperature[8], followed by FAB–MS examination. The spectrum produced is shown in Fig. 1.

The appearance of a 1:1 signal (containing an acetyl group) at *m/e* 1,183 suggested that the N-terminus was not blocked, although abnormal acetylation of a very reactive guanidino group could not be eliminated at this stage. (Spinning-cup sequencer studies on the related SCP_A proved negative suggesting a possible blocked N-terminus). Importantly, the presence of weak 1:1 doublets throughout the spectrum now allowed a partial sequence of SCP_B to be built up by looking for meaningful mass differences based upon empirical FAB fragmentation mechanisms[4]. For example, the doublets at *m/e* 242, 288, 451, 564, 635, 724, 782 and 811 were spotted and have been marked on Fig. 1 for clarity. Not all of these led to readily interpretable mass differences but the signals at *m/e* 288, 451, 564, 635 and 782 gave a tentative partial sequence of

$$X^{288}\text{—Tyr-Leu-Ala-Phe—}Y$$

(where X and Y denote unknown portions of the molecule). Note that the signals at *m/e* 724 and 811 are not assigned and in fact were never used in the sequence assignment. They were assumed to be quasimolecular ions of contaminating peptides and this was later confirmed by their absence from the spectrum of the synthetic peptide.

At this stage, 1 μg of SCP_B was digested with trypsin *p*H 8.3 (1:50 enzyme to substrate, at 37 °C for 1 h) and the digest examined directly by FAB–MS. This experiment was crucial for the interpretation of the structure (Fig. 2). A new quasimolecular ion is seen at *m/e* 1,011, concomitant with the disappearance of the original signal at *m/e* 1,141. The new peptide giving rise to the 1,011 signal would be expected to contain a C-terminal arginine residue and its high mass placed that arginine towards the C-terminal end of the molecule. However the mass difference of 130 AMU lost on digestion does not correspond to any single amino acid or combination of amino acids. However, the mass difference is just one atomic mass number away from the mass of methionine. If we then postulate that SCP_B has a blocked amidated C-terminus, the tryptic digestion process would liberate a free carboxyl group from a previously amidated extended sequence, thus accounting for the one atomic mass unit and we therefore deduced that the SCP_B peptide contained a C-terminal-Arg-Met-NH_2 unit.

Because the 1:1 labelled signals (*m/e* 288 etc.), which appear to be derived from partial sequence -Tyr-Leu-Ala-Phe-, were not C-terminal ions extending N-terminally from the Arg-Met-amide sequence, it then followed that the label could not be on the arginine but was on the amino terminus and thus SCP_B was not N-terminally blocked.

Using this information we looked for C-terminal sequence ions in Fig. 1 and noted signals at *m/e* 549, 620, 733, 896 and

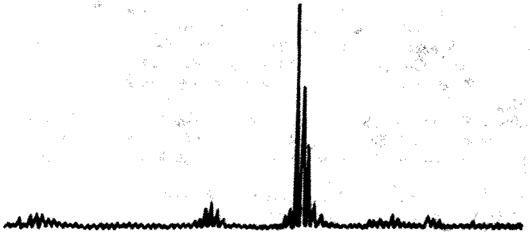

Fig. 2 Molecular ion region of the fast atom bombardment mass spectrum of the tryptic digest of SCP_B (1 μg), showing the presence of a quasimolecular ion $(M+H)^+$ at *m/z* 1,011.

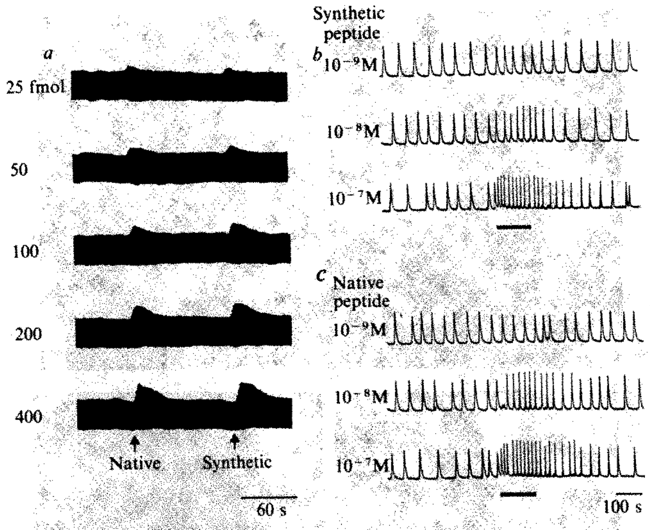

Fig. 3 A comparison of the biological activities of native and synthetic SCP$_B$s on two preparations. *a*, Pulse applications of 25–400 fmol of the peptides to an isolated snail heart. Native and synthetic peptides caused similar increases of the amplitude of heart beat contractions at each concentration. *b*, *c*, Superfusion of an isolated snail oesophagus with 10^{-9}–10^{-7} M synthetic SCP$_B$ (*b*), and native SCP$_B$ (*c*). The contractile activity of the oesophagus represents rearward directed peristalses which increase in frequency when either the synthetic or native SCP$_B$ is present in the bath (at horizontal bars).

1,010. These signals are all accompanied by satellites 15 AMU lower corresponding to the alkyl rather than the amine fragment with the charge on the C-terminus. This pattern often facilitates the identification of C-terminal sequence ions. By interpreting mass differences the sequence -Asn-Tyr-Leu-Ala has been generated.

The unknown unit 'X' on the N-terminal side of the tyrosine residue had a mass of 288 AMU, so by using C-terminal signals we have deduced that one component of this signal is asparagine. It now follows by mass difference that the N-terminal amino acid of SCP$_B$ is methionine, thus giving a structure H-Met-Asn-Tyr-Leu-Ala-.

Combining these data with the N-terminal assignment and trypsin experiment now extends the sequence to

H-Met-Asn-Tyr-Leu-Ala-Phe[···]Arg-Met NH_2

Using similar logic to that above, on any of the C-terminal signals, for example *m/e* 549, and subtracting the masses of Phe, Arg and Met amide, we conclude that the bracketed gap in the sequence above has a mass difference of 97 AMU which corresponds to proline. This assignment is confirmed by the observation of a signal at *m/e* 402 corresponding to the C-terminal signal Pro-Arg-Met-amide. Note that there is no satellite 15 AMU away, as would be expected since proline has a tertiary nitrogen, and cannot fragment to give an alkyl unit.

A combination of all the above analyses gives the structure of SCP$_B$ as the C-terminally blocked nonapeptide

H-Met-Asn-Tyr-Leu-Ala-Phe-Pro-Arg-Met-NH_2

The peptide was synthesised via *t*-butyloxycarbonyl (Boc) ester intermediates[9] using *N,N*-dicyclohexylcarbodiimide-1-hydroxybenzotriazole coupling[10]. The amide group was introduced at the Boc-Pro-Arg-Met methyl ester stage by treatment with methanolic ammonia. The protected nonapeptide was purified by countercurrent distribution and deprotected in 90% TFA. Reverse-phase HPLC showed that the synthetic peptide was 95–97% pure, and that it precisely co-eluted with the native peptide.

The biological activities of the native and synthetic peptide were compared on two types of preparation; isolated heart and oesophagus from snails. The isolated snail heart is the most quantitative of the available assays for SCP$_B$ but responds in similar fashion to the application of other substances such as other neuropeptides and serotonin[5]. In contrast, the isolated snail oesophagus is less quantitative but responds in a qualitatively different fashion to SCP$_B$, other neuropeptides and serotonin[1]. Native and synthetic peptides were quantified by amino acid analysis and applied in known amounts to the heart (Fig. 3*a*) and oesophagus (Fig. 3*b*). These results demonstrate that the active and synthetic peptides are quantitatively and qualitatively identical. We have also carried out some preliminary experiments which indicate that synthetic SCP$_B$ also excites the isolated *Aplysia* heart (threshold 10^{-11} M). Together with the FAB-MS analysis of synthetic SCP$_B$ these data confirm that the presented sequence is correct.

It is interesting to note that (1) our sequence terminates with several hydrophobic residues, (2) the penultimate residue is arginine, and (3) the C-terminus is amidated. This is strikingly similar to another molluscan cardioactive peptide, Phe-Met-Arg-Phe-amide[11]. Our work indicates that a new peptide class may exist, the key unit for biological activity being

Phe-A-Arg-B-amide

(where A and B are also hydrophobic amino acids), and probes designed with such a sequence may be valuable in the search for related peptides. Recent reports have suggested that there may be considerable conservation of neuropeptides between invertebrates and mammals, and there are a number of interesting cases where the original elucidation of a peptide class was carried out in an invertebrate. Examples of this include eledoisin (a tachykinin) from octopus[12], FRMF-amide from clam[13] and head-activating peptide from *Hydra*[14]. It will therefore be important to ascertain if peptides related to SCP$_B$ are present in other animals including mammals.

The precise physiological role of SCP$_B$ has not been determined in any gastropod mollusc, but it appears likely that it is involved in the control of gut activity[1,5]. In addition its marked potency in exciting many different muscle preparations suggests that it may be involved in a more general arousal in these animals.

Finally, we note that mass spectrometry, whilst previously essential in the elucidation of such structures as the enkephalins[15], leukotriene D[16] and adipokinetic hormone[17], has now improved in sensitivity by at least an order of magnitude. Although FAB-MS rarely gives complete sequence information at the 1 nanomole level, this paper demonstrates how a complete unknown sequence can be generated by judicious use of enzyme digests and micro-scale derivatization.

We thank Kenneth Walsh, in whose laboratory some of the HPLC and amino acid analyses were carried out, and Tony Etienne who quantified the synthetic peptide by HPLC and amino acid analysis. We also thank David McAdoo and colleagues for help with collection and dissection of animals. This work was supported by the MRC (UK) and NSF BNS 79-06820 NJH R01 MH 36730, R01 MH 35564 (USA).

Lectin binding reveals a synapse-specific carbohydrate in skeletal muscle

Joshua R. Sanes & Jeanette M. Cheney

Department of Physiology and Biophysics, Washington University
School of Medicine, St Louis, Missouri 63110, USA

Molecules concentrated at synapses are of interest because they may have roles in synaptic development or function. Several 'synapse-specific' proteins have been identified at the skeletal neuromuscular junction; acetylcholine (ACh) receptors[1], acetylcholinesterase[2], some components of the basal lamina[3] and a number of cytoskeletal elements[4,5], are all present at far higher concentrations at synaptic sites than elsewhere on the muscle fibre surface. As carbohydrates are thought to be involved in neuronal recognition, adhesion and synaptogenesis[6-12], we have asked whether any saccharide moieties are similarly concentrated at synaptic sites on muscle fibres. Lectins are proteins that bind to carbohydrates; each has its own sugar specificity[13,14]. Fluorescent and other derivatives of lectins have been used as histochemical stains to study the nature and distribution of carbohydrates on many cell types[13-16] including neurones[6,7,17-19] and muscle fibres[16,20]. We report here that the lectin from the legume *Dolichos biflorus*, DBA, selectively stains neuromuscular junctions in several vertebrate species. This result demonstrates the existence of a synapse-specific carbohydrate.

Cryostat sections of unfixed skeletal muscle were incubated with fluorescein-conjugated lectins and viewed by fluorescence optics. Fluorescein–DBA stained only a few discrete spots on the surface of rat muscle fibres (Fig. 1*a*). Double staining with rhodamine-α-bungarotoxin, which binds to ACh receptors in the postsynaptic membrane[1,3-5], showed that the DBA-stained patches were synaptic sites (Fig. 1*b*,*c*); no other structures identifiable in cross-sections were stained by this lectin. Fluorescein–DBA also stained neuromuscular junctions specifically and intensely in cryostat sections of rabbit, hamster and chick muscle; frog (*Rana pipiens*) neuromuscular junctions were faintly, but selectively stained. Thus, DBA recognizes molecules that are highly concentrated or especially accessible at the neuromuscular junction.

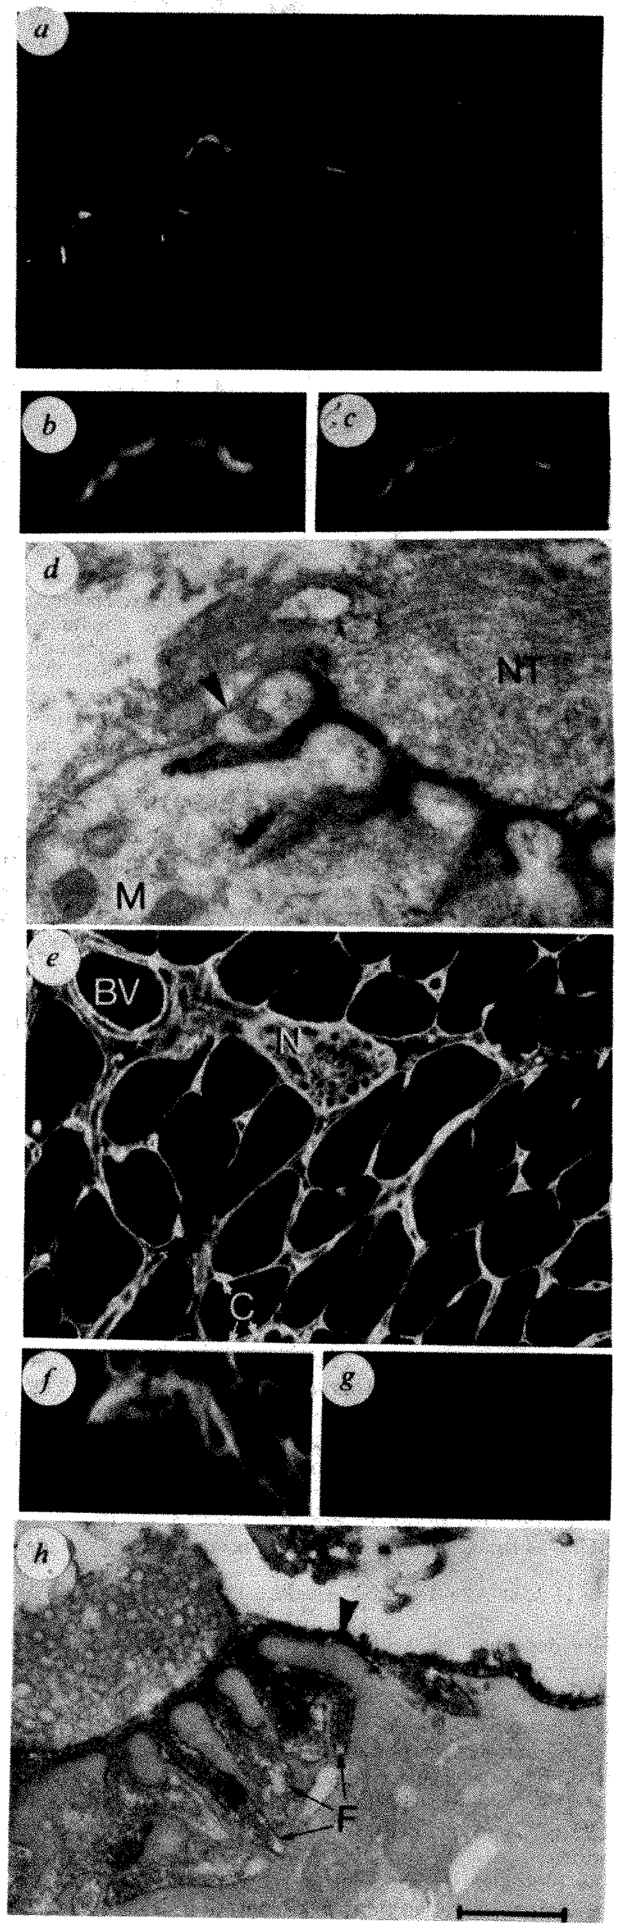

Fig. 1 *a–c*, Staining of rat neuromuscular junctions by fluorescein–DBA. Cross-sections of frozen, unfixed rat diaphragm were incubated for 30 min with a mixture of fluorescein–DBA (E-Y Laboratories) and rhodamine-α-bungarotoxin, then photographed with appropriate filters to show fluorescein (*a*, *b*) or rhodamine (*c*). Rhodamine–bungarotoxin binds to ACh receptors in the postsynaptic membrane and thus marks synaptic sites[3-5]. *b* and *c* show the same field; the coincidence of fluorescein and rhodamine demonstrates that DBA stains synaptic sites. Similar results were obtained with fluorescein–DBA from Polysciences, and with biotin–DBA plus fluorescein–avidin from Vector Laboratories. *d*, Electron micrograph of a neuromuscular junction from a rat intercostal muscle incubated with peroxidase–DBA, then washed, fixed and stained for peroxidase (see ref. 27 for details). Reaction product is present in the synaptic cleft between the nerve terminal (NT) and muscle fibre (M), and in junctional folds (F; see *h*), but not on extrasynaptic portions of the muscle fibre surface (arrowhead). No staining was detectable when muscles were incubated without lectin. *e–h*, Sections prepared as in *a–d*, but stained with *Ricinus communis* I lectin. This lectin stains both synaptic and extrasynaptic portions of the muscle fibre surface, as well as surfaces of blood vessels (BV), capillaries (C), and axons and perineural sheaths of intramuscular nerve trunks (N). Scale bar, 50 μm in *a* and *e*; 10 μm in *b*, *c*, *f* and *g*; 0.5 μm in *d*; and 0.4 μm in *h*.

0028-0836/82/500646—02$01.00

DBA is a lectin that recognizes N-acetylgalactosaminyl (GalNAc) termini of oligosaccharide chains[13,21]. Three results provide evidence that the staining of rat neuromuscular junctions by fluorescein–DBA represents binding of the lectin to a synapse-specific carbohydrate that contains or resembles Gal-NAc. First, staining was abolished by addition of 20 mM Gal-NAc to the incubation medium (Fig. 2*a*) but persisted in the presence of 100 mM, D-glucose, D-galactose, N-acetylglucosamine or α-methylmannoside. Thus DBA binds to synapses via its GalNAc-binding site. Second, two other lectins that recognize GalNAc residues, *Glycine max* (soybean) lectin and *Vicia villosa* lectin, stained synaptic sites intensely. These two lectins also stained the extrasynaptic muscle fibre surface faintly, possibly because they are less discriminating than DBA in their preference for GalNAc over other sugars[21,22]. Finally, lectins that recognize three other sugars do not distinguish synaptic from extrasynaptic regions; concanavalin A, wheatgerm agglutinin, and *Ricinus communis* I lectin (staining blocked by α-methylmannoside, N-acetylglucosamine and D-galactose, respectively) all stained both synaptic and extrasynaptic portions of the muscle fibre surface as well as the surfaces of blood vessels, capillaries, myelinated axons and intramuscular nerve sheaths (Fig. 1*e*–*h*). This result shows that specific staining of neuromuscular junctions by DBA is not due to an overall disproportion of carbohydrate at synaptic sites.

Further histochemical studies of rat muscle elucidated the localization of the synaptic component(s) to which DBA binds. Electron microscopy of muscle stained with peroxidase–DBA revealed reaction product in the synaptic cleft and in junctional folds but not elsewhere on the muscle fibre surface (Fig. 1*d*), confirming that this lectin binds selectively to synaptic sites. As muscles were incubated with peroxidase–DBA while alive, then washed, fixed and stained[3], at least some DBA receptors must be external to the protein-impermeable plasma membrane. Staining persisted without any apparent diminution in denervated muscle (Fig. 2*b*), demonstrating that DBA receptors are not confined to the nerve terminal, but are present on the muscle fibre surface. DBA also stained synaptic sites after muscle was subjected to either of two treatments that remove cytoplasm and plasma membrane but not the basal lamina, that is; damage-induced degeneration and phagocytosis of muscle fibres (Fig. 2*c*) or salt and detergent extraction of sliced muscle[3]. This shows that some DBA receptors are associated with the basal lamina of the synaptic cleft; it does not, however, exclude the possibility that DBA also binds to some components of the plasma membrane. (Some receptors for concanavalin A, wheatgerm agglutinin and *Ricinus communis* I lectin also survived muscle damage and thus are associated with basement membrane in muscle, as they are in kidney[23].)

The identity and function of the DBA receptor(s) we have stained are unknown. GalNAc-binding lectins recognize glycoproteins, glycolipids and glycosaminoglycans[13,21,24], any or all of which might be concentrated at synaptic sites. Among many possible roles for the DBA-binding carbohydrates are targeting of molecules to synaptic sites[12], adhesion of nerve and muscle[6], and recognition of synaptic sites by nerve terminals[25]. An intriguing idea is that there is an endogenous lectin[8,24] at the synapse which, in concert with the DBA receptor, plays some part in the formation or function of the neuromuscular junction.

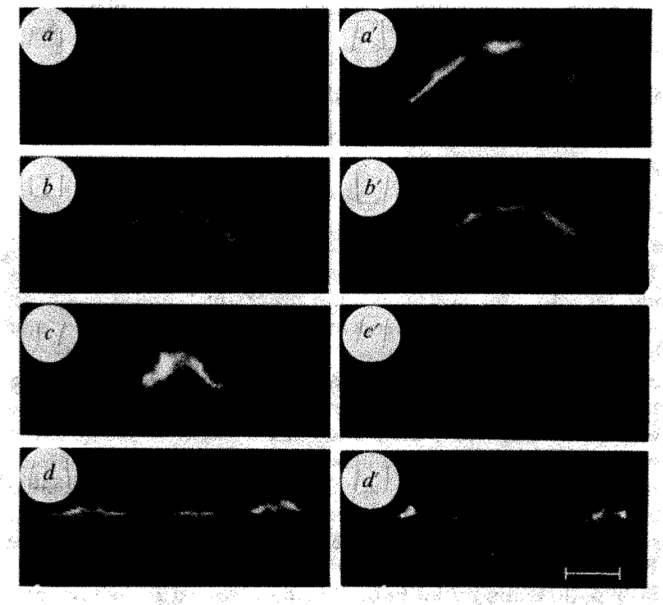

Fig. 2 Characteristics of DBA receptors in muscle. Muscles were doubly-labelled with fluorescein–DBA (or biotin–DBA followed by fluorescein–avidin) and rhodamine–bungarotoxin, as described in Fig. 1 legend. Each pair of micrographs shows the same field photographed with fluorescein- (*a*–*d*) and rhodamine- (*a'*–*d'*) selective filters. *a*, *a'*, Cryostat section of normal rate diaphragm stained in the presence of 20 mM GalNAc. The hapten sugar has blocked staining of the synaptic site by DBA; compare with Fig. 1*b*, *c*. *b*, *b'*, Cryostat section of rat diaphragm denervated 2 weeks earlier. Nerve terminals have degenerated and been removed, but DBA still stains synaptic sites. *c*, *c'*, Cryostat section of rat intercostal muscle that had been damaged[3] and denervated 3 days earlier. Nerve and muscle membranes have degenerated, and bungarotoxin-binding sites have disappeared, but basal lamina sheaths of muscle fibres survive (see refs 3, 27 for details); DBA stains synaptic sites on the sheaths. In other experiments, such DBA-stained patches were positively identified as synaptic sites by double staining with an antibody to a synapse-specific component of muscle fibre basal lamina[3]. *d*, *d'*, Myotube from a chick nerve-muscle co-culture prepared as described by Fischbach[28] (provided by Drs L. Role and G. Fishbach). DBA binds to ACh receptor-rich patches on the myotube surface. Scale bar, 10 μm.

These possibilities are best tested *in vitro*. In initial studies, we have found that fluorescein–DBA binds selectively (although not exclusively) to ACh receptor-rich regions of the myotube surface in chick nerve–muscle co-cultures (Fig. 2*d*); some of these patches are synaptic sites[26].

Thus, we have shown that the plant lectin DBA binds specifically to synaptic sites on the surface of skeletal muscle fibres; to our knowledge, this is the first demonstration of a carbohydrate moiety specifically localized at a synapse in any tissue. DBA should be a useful tool with which to study the identity, metabolism and function of this carbohydrate. In addition, DBA can serve as a simple light and electron microscopic stain for neuromuscular junctions.

Sex differences in rat brain oestrogen and progestin receptors

Thomas C. Rainbow*, **Bruce Parsons** & **Bruce S. McEwen**

The Rockefeller University, 1230 York Ave, New York,
New York 10021, USA

The brains of both male and female rats possess specific cytoplasmic receptors for oestrogens and progestins[1], and it has been suggested that sex differences in the neuroendocrine and behavioural responses to these hormones result from differences in the number of steroid receptors in specific locations in the brain[2]. Although there have been numerous comparisons of steroid receptors in male and female brains[3–9], the question of whether there are sex differences in these receptor systems remains unresolved, due in part to the inability of available biochemical techniques to achieve sufficiently high anatomical resolution. We have overcome this problem by applying the Palkovits punch-out technique[10] to measure steroid receptors in hypothalamic nuclei known to be involved in behavioural and neuroendocrine control. We report here that castrated male rats have fewer oestrogen and progestin receptors in certain hypothalamic nuclei than females. This suggests that the relative insensitivity of male rats to feminine actions of gonadal steroids might be due in part to a lack of receptors for these steroids in highly localized brain regions.

Hypothalamic nuclei were removed from frozen, 300-μm thick brain sections, using hollow stainless steel cannulas, 500 or 1,000 μm in diameter. We pooled tissue from three ovariectomized or castrated rats (CD-1 strain, Charles River Biological Laboratories; 150–180 g) for an assay. For measurement of progestin receptors, all rats received subcutaneous (s.c.) injections of 10 μg oestradiol benzoate (OB) once a day for 3 days before killing; this treatment induces hypothalamic progestin receptors to high levels[11,12]. Rats were perfused through the heart with 10% ice-cold dimethyl sulphoxide to protect steroid receptors against loss from freezing[13]. We removed from the brain sections portions of the bed nucleus of the stria terminalis, the medial preoptic nucleus, the periventricular region of the preoptic area and of the anterior hypothalamic nucleus, the ventromedial nucleus and the arcuate nucleus. These six nuclei and their subregions were examined because they have the highest concentrations of gonadal steroid receptors in the brain[14,15], and have been extensively implicated in the behavioural and neuroendocrine actions of steroids[16]. The number of oestrogen and progestin receptors was measured in cytoplasmic fractions of the nuclei by the specific binding of ^{3}H-OE$_2$ (115 Ci mmol^{-1}, NEN) and ^{3}H-R5020, a potent synthetic progestin (87 Ci mmol^{-1}, NEN). Cytosol protein (8–50 μg) was incubated with 1 nM ^{3}H-OE$_2$ or 0.4 nM ^{3}H-R5020 at 4 °C for 4 h. For each nucleus, the amount of protein in the incubate was the same for males and females (Table 1). Non-specific binding was measured by co-incubation with 1 μM moxestrol or 0.1 μM R5020, respectively. The ^{3}H-steroid bound to receptors was separated from free ^{3}H-steroid by gel filtration on Sephadex LH-20 columns[11–15]. The amount of protein in the incubate was determined by the method of Bradford[17]. The levels of oestrogen and progestin receptors in brain samples were expressed as steroid specifically bound per mg protein.

In preliminary studies, we observed a qualitatively similar distribution of gonadal steroid receptors in male and female brains. The highest levels of both oestrogen and progestin receptors in either sex were found in the periventricular region of the preoptic area, with substantial levels of binding also observed in the arcuate, medial preoptic and ventromedial hypothalamic nuclei, and in the periventricular region of the anterior hypothalamic nucleus. The bed nucleus of the stria terminalis showed high oestrogen binding, but low levels of progestin receptors. We observed moderate amounts of gonadal steroid receptors in the anterior hypothalamic nucleus, the dorsomedial nucleus of the hypothalamus, and the medial nucleus of the amygdala. Both males and females had low levels of receptors in the lateral preoptic nucleus, the nuclei of the septum and the diagonal band of Broca. We also observed similar, low levels of uninduced progestin receptors in males and females.

Although the general receptor distribution was the same for males and females, there were substantial quantitative sex differences in the receptor content of specific nuclei (Fig. 1). The medial preoptic nucleus, which may be the target region for oestrogen-induced control of gonadotropin release[16], had less than half the level of oestrogen receptors in males as in females (7×10^{-15} as opposed to 17×10^{-5} m (moles) per mg protein). There was a large sex difference in the progestin receptor content of the ventromedial nucleus, with oestrogen-treated male rats having less than 30% of the receptor levels of oestrogen-treated females (8 as opposed to 25×10^{-15} mol

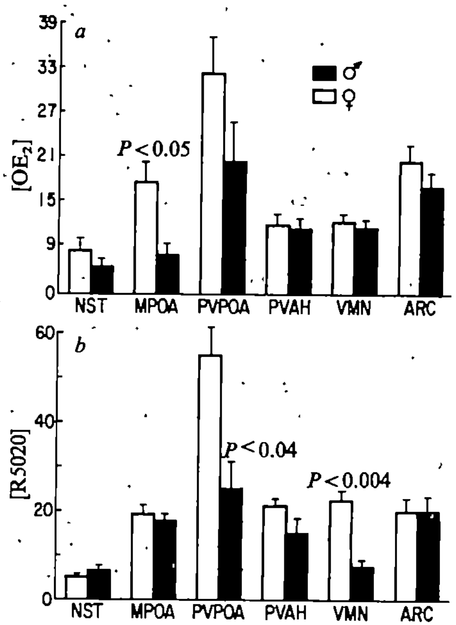

Fig. 1 Oestrogen and progestin receptor levels in hypothalamic nuclei of male and female rats. Rats were gonadectomized at least 1 week and not more than 3 weeks before assays were performed. Males and females were assayed together and were matched for age and length of time after gonadectomy. Steroid receptor levels were measured in hypothalamic nuclei by the specific binding to cytosol fractions of ^{3}H-oestradiol (*a*) and ^{3}H-R5020, a synthetic progestin (*b*). Tissue from hypothalamic nuclei was homogenized in 240 μl of TEGD buffer (10 mM Tris-HCl, 5 mM EDTA, 10% glycerol and 1 mM dithiothreitol *p*H 7.4). The cytosol fraction of the homogenate was obtained by centrifugation in a Beckman Airfuge at 100,000*g* for 20 min. 100 μl of cytosol were added to 50 μl of TEGD buffer containing ^{3}H-steroid plus unlabelled competitors. A 100-μl aliquot of the incubate was applied to a Sephadex LH-20 column for gel filtration. The column was eluted with 400 μl TEG buffer (TEGD buffer without dithiothreitol) 30 min after the sample was applied. The radioactivity in the eluate was measured by liquid scintillation counting at 34% efficiency. The level of nonspecific binding corresponded to no more than 25% of the total binding. Progestin receptor measurements were made in rats given oestradiol benzoate. Possible sex differences in non-oestrogen-induced progestin receptors were not examined because most of the neural actions of progesterone in females require oestrogen priming, and either require or are strongly correlated with oestrogen-induced progestin receptors[3]. Values are expressed as concentration of steroid ($\times^{-15}$ mol) specifically bound per mg protein· $n=9$ for paired comparisons of oestrogen receptor levels in males and females; $n=6$ for paired comparisons of progestin reeptor levels. Significant sex differences were seen in oestrogen receptor levels in the medial preoptic area ($P=0.045$, 2-tailed paired *t* comparison), in progestin receptors in the periventricular preoptic region ($P=0.037$) and in the ventromedial nucleus ($P=0.003$). There were no other significant sex differences in receptor content ($P>0.120$ for all nuclei, 2-tailed paired *t*-test). NST, bed nucleus of the stria terminalis; MPOA, medial preoptic area; PVPOA, periventricular region of the preoptic area; PVAH, periventricular portion of the anterior hypothalamic nucleus; VMN, ventromedial ucleus; ARC, arcuate nucleus.

Table 1 Location and protein content of hypothalamic nuclei

Region	Stereotaxic location	Protein (mg) Male	Protein (mg) Female
Bed nucleus stria terminalis	A7,190–6,290 μm	0.024±0.001	0.026±0.001
Medial preoptic nucleus	A7,190–6,590 μm	0.021±0.001	0.020±0.001
Periventricular preoptic nucleus	A7,190–6,590 μm	0.012±0.001	0.012±0.001
Periventricular anterior hypothalamic nucleus	A6,590–5,690 μm	0.018±0.002	0.017±0.001
Ventromedial nucleus	A4,890–3,690 μm	0.042±0.002	0.045±0.002
Arcuate nucleus	A4,890–3,690 μm	0.037±0.003	0.035±0.003

Nuclei were removed from frozen 300-μm thick sections of male and female rat brain, according to the procedure of Palkovits[10], using a 500 or 1,000 μm diameter stainless steel cannula. The medial preoptic and ventromedial nuclei were removed with bilateral 1,000 μm punches. The periventricular anterior hypothalamic nucleus was taken with a single 1,000 μm punch, placed over the dense area of ^{3}H-OE$_2$ binding described in the autoradiograms of Pfaff[16]. The bed nucleus of the stria terminalis was dissected with bilateral 500 μm punches above and below the decussation of the anterior commissure, and with bilateral 1,000 μm punches caudal to this. The periventricular preoptic region and the arcuate nucleus were removed with a small scalpel. The locations of nuclei are taken from the stereotaxic atlas of Konig and Klippel[21]. The protein values are the mean±s.e.m. of the amount of cytosol protein applied to Sephadex LH-20 columns for steroid receptor measurements (see text for details). Protein was measured by the method of Bradford[17]; $n = 15$ for both males and females.

per mg protein). The level of progestin receptor in the male ventromedial nucleus after OB treatment was comparable to unstimulated (non-OB-treated) levels in the female ventromedial nucleus[15]. The ventromedial nucleus of the hypothalamus may be the principal target site in rat brain for the activation of proceptive and receptive sexual behaviour by progesterone[3]. The periventricular region of the preoptic area also showed a significantly lower level of progestin receptor in males than in females (25 as opposed to 50×10^{-15} mol per mg protein). There were no other significant sex differences in oestrogen or progestin receptor content among the six nuclei examined (Fig. 1).

The sex differences in certain regions having a high content of oestrogen and progestin receptors could explain particular sex differences in sensitivities to gonadal steroids. The substantially lower level of oestrogen receptors in male medial preoptic nucleus might explain in part why luteinizing hormone (LH) release in male rats is not stimulated by oestrogen. The local implantation of oestrogen into the medial preoptic area will stimulate LH release, while ablation of the medial preoptic nucleus blocks the LH surge[16]. The very low level of progestin receptors in the ventromedial nucleus after oestrogen treatment may explain the inability of progesterone to produce proceptive behaviours and increase receptivity in oestrogen-primed males[3]. The implantation of nanogramme amounts of progesterone into the ventromedial nucleus will facilitate lordosis and activate sexual proceptivity in oestrogen-primed females[18]. The same small quantities of progesterone have no effect on sexual behaviour when applied to other hypothalamic nuclei. The effects of progesterone can also be blocked by the local application of a protein synthesis inhibitor to the ventromedial hypothalamus[19]. There is little information on the possible functions of the high level of progestin receptors in the periventricular preoptic area, thus the significance of the large sex difference in this region is unclear. It is possible that sex differences also exist in brain regions with a low to moderate amount of gonadal steroid receptors. These regions were not examined in the present study.

Sex differences in oestrogen and progestin receptors do not necessarily occur in the same nuclei (Fig. 1). In the medial preoptic area, the difference in oestrogen receptor content is not accompanied by a sex difference in progestin receptors: It may be that the subset of oestrogen-sensitive cells which make progestin receptors are not sexually dimorphic. Conversely, the sex differences in progestin receptors in the ventromedial and periventricular preoptic nuclei are not accompanied by a sex difference in oestrogen receptors; it is possible that the process of progestin receptor induction has been suppressed in these nuclei during sexual differentiation.

In previous studies on whole regions of the hypothalamus and preoptic area[3,4], we found no sex differences in cytoplasmic oestrogen and progestin receptors. The amount of steroid receptor in an individual nucleus is a small part of the total amount of receptor in a hypothalamic tissue block, thus it is not surprising that sex differences were not detected in these studies. Our measurements of cytoplasmic receptor levels do not exclude the possibility that sex differences also exist in the translocation of gonadal steroid receptors to cell nuclei. There are several reports of sex differences apparent in whole hypothalamic blocks of rat brain, when the nuclear retention of ^{3}H-oestradiol is measured[5–7], although other laboratories have found similar levels of nuclear uptake in males and females[8,9]. The measurement of cell nuclear receptor levels for gonadal steroids in microdissected brain regions would clarify the existence of sex differences in nuclear uptake. Note also that in order to minimize binding to low-affinity progestin sites[12], we used a concentration of ^{3}H-R5020 that occupies only 70–80% of the high-affinity component of the binding. Until we are able to perform binding isotherms on the limited amount of receptor in a punch-out sample, it remains possible, although unlikely, that the rather large male–female differences in ^{3}H-R5020 binding represent differences in affinity rather than differences in concentration.

It is possible that regionally localized sex differences in gonadal steroid receptors exist in the brains of many species. Using quantitative autoradiography, Arnold and Saltiel[20] have found sex differences in the nuclear uptake of androgens in the song control nuclei of zebra finch brain. Their results and those presented here indicate that sex differences in neural receptors for gonadal steroids could be a general consequence of sexual differentiation, and may even exist in steroid-concentrating regions of human brain.

A circulating inhibitor of $(Na^+ + K^+)$ATPase associated with essential hypertension

The aetiology of essential hypertension, a disease prevalent in cultured societies, is unknown. However, much evidence suggests that abnormal sodium metabolism has a critical role—this has led to the hypothesis that an increase in the circulating concentration of an inhibitor of $(Na^+ + K^+)$ATPase is responsible for the increased peripheral vascular resistance in essential hypertension[1]. Evidence for relatively high levels of a Na^+ pump inhibitor in essential hypertension has come from bioassay and cytochemical assays of plasma and urine from normotensive and hypertensive individuals[2,3]. There is also evidence for increased plasma levels of a Na^+ pump inhibitor in some animal models (for example, renal and deoxycorticosterone acetate (DOCA) models) of hypertension[4]. Nevertheless, direct biochemical determination of $(Na^+ + K^+)$ATPase inhibition by this substance has not yet been reported. We demonstrate here, with a kinetic $(Na^+ + K^+)$ATPase assay, a highly significant correlation between levels of a plasma inhibitor of $(Na^+ + K^+)$ATPase activity and mean arterial blood pressure (MAP) in normotensive and hypertensive individuals. These data provide evidence for the involvement of a circulating Na^+ pump inhibitor in the genesis of essential hypertension. Moreover, our assay methods may be useful for the isolation and characterization of this inhibitor.

We have tested the effect of deproteinized blood plasma samples on the activity of a partially purified canine kidney $(Na^+ + K^+)$ATPase. In our assay, the regeneration of enzymatically hydrolysed ATP is coupled to the oxidation of NADH so that the action of various inhibitors can be monitored by continuously recording the absorbance of NADH at 340 nm. As we are concerned here with the activity of a humoral inhibitor of $(Na^+ + K^+)$ATPase, we compared it with the behaviour of two well characterized inhibitors of the ATPase; Fig. 1*a* shows the features of inhibition by ouabain. This cardiotonic steroid had no significant effect on the reaction for the first 30 s, and thereafter caused a progressive, dose-dependent increase in inhibition[5]. Steady-state levels of inhibition were not achieved in the short time course presented. Similarly, the inhibition by vanadate (Fig. 1*b*) increased with time[6], but because of the much faster association rate constant for binding, an effect of vanadate was apparent during the first few seconds of the reaction, especially at higher concentrations. By measuring the steady-state levels of $(Na^+ + K^+)$ATPase activity in the presence of various vanadate concentrations, we estimate a K_i of 0.9 μM, in agreement with published values[7,8].

Figure 1*c* shows the kinetic behaviour of $(Na^+ + K^+)$ATPase assayed in the presence of a saline solution (control) and deproteinized plasma samples derived from one normotensive individual, and from a patient with essential hypertension. In each case, about 1.5 min were required to reach a steady state of enzyme activity, which then lasted for at least 10 min (not shown). The normotensive NT plasma produced (in this

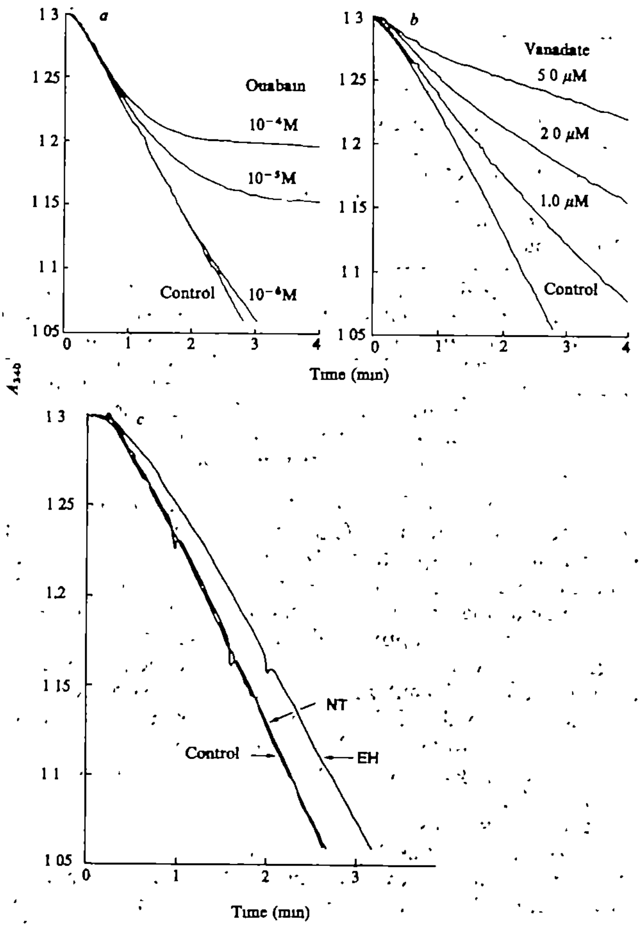

Fig. 1: Inhibition of $(Na^+ + K^+)$ATPase activity by ouabain (*a*), vanadate (*b*), and plasma samples (*c*). Canine kidney $(Na^+ + K^+)$ATPase was obtained from Sigma (specific activity 5–6 μmol per min per mg protein). This preparation also contained an ouabain-insensitive Mg^{2+}-ATPase activity which was less than 2% of the total steady-state ATPase activity. The ATPase assay consisted of 400 μl ATPase cocktail to which 580 μl of H_2O were added Final reaction conditions were (in 1.0 ml) as follows (in mM or appropriate units)· KCl 20; NaCl 100; $MgSO_4$ 4.5; EGTA 5; Na_2ATP 3; phosphoenolpyruvate tricyclohexylammonium (PEP), 1.2, NADH, 0.25; TES–Tris, 40, *p*H 7.4; lactate dehydrogenase (LDH), 1.2 U, pyruvate kinase (PK), 1.2 U. ATP, PEP, NADH, LDH and PK were from Boehringer Mannheim Biochemicals; both enzymes were obtained as glycerol suspensions. $(Na^+ + K^+)$ATPase was prepared for assay by suspension in 500 μM Na_4EDTA, 10 mM trimethylaminoethanesulphonic acid (TES)–Tris *p*H 7.4, at a protein concentration of 150 μg ml^{-1}. The resuspended enzyme was incubated at 25 °C for 3 h, and then stored on ice; the activity of the ATPase thus prepared does not change by more than 1% during the following 20 h on ice. The assay was initiated by rapid addition of 20 μl of ATPase suspension (3 μg protein) to 980 μl of reaction cocktail in a 1.0-ml cuvette at 37 °C, and the decrease in A_{340} due to NADH oxidation ($\varepsilon = 6.22 \times 10^3 \, l \, mol^{-1} \, cm^{-1}$) was continuously recorded, as illustrated in the examples shown here. *a*, Ouabain (1-μl aliquots of stock solutions prepared in dimethyl sulphoxide, DMSO) was pre-added to the reaction cocktail to give the final concentrations indicated. Controls contained appropriate quantities of DMSO. *b*, Vanadate, as Na_3VO_4, was freshly prepared in H_2O and similarly pre-added to the reaction. Neither ouabain nor vanadate, at the concentrations shown, had any significant effect on the efficacy of the regenerating system, as determined by inspection of rates of NADH oxidation in response to addition of 10–50 μM ADP. The activity of the regenerating system was found to be over 70-fold greater than that of the total ATPase activity in these conditions. *c*, Effect of two individual plasma samples on the ATPase activity. Conditions were similar to those for *a* and *b* except that the assay cocktail contained (in mM): $MgSO_4$, 9; and $CaCl_2$, 2. 500 μl of H_2O were replaced by an equivalent volume of deproteinized plasma (see Fig. 2 legend) obtained from a normotensive individual (NT) or a patient with essential hypertension (EH). The control contained, in addition to the assay cocktail, 500 μl of a solution of the following composition (in mM). KCl, 2.1; NaCl, 120; $NaHCO_3$, 26; $CaSO_4$, 2.5; K_2HPO_4, 1.2; $MgSO_4$, 1.2; EGTA, 3.4, EDTA, 2.8; and 800 μg ml^{-1} bovine serum albumin. The EDTA and EGTA were included in this solution to control for their presence as anticoagulants in the plasma samples; see Fig. 2 legend for details. All the curves shown were traced from original records. Per cent inhibition was calculated as:

$$100 - \left(\frac{\text{sample } \Delta A_{340} \text{min}^{-1}}{\text{control } \Delta A_{340} \text{min}^{-1}}\right) \times 100.$$

0028-0836/82/500650—03$01 00

example) no inhibition of activity compared with the control. In contrast, the hypertensive sample produced a 14% inhibition of steady-state activity which remained constant for the next 10 min of the reaction. This result demonstrates the presence of an increased level of an inhibitor of $(Na^+ + K^+)$ATPase in hypertensive plasma that has a rapid-onset of action in contrast to ouabain and vanadate.

This technique (see Fig. 1 legend) was used to assay plasma samples from 20 normotensive individuals and 26 patients with essential hypertension. A significant correlation between MAP and $(Na^+ + K^+)$ATPase inhibition was found when the hypertensive group alone was analysed ($r = 0.46, P < 0.01$); no significant correlation was found for the normotensive group. However, inclusion of the normotensives in the overall analysis (as illustrated) resulted in greater correlation coefficient and significance values ($r = 0.73, P < 0.0005$). Slightly smaller correlation coefficients ($r = 0.69$ and 0.68, respectively), but similar P values, were obtained when the data from blacks and whites were evaluated separately. The correlation was similar ($r = 0.77, P < 0.0005$) when diastolic pressure was used instead of MAP. There was no significant correlation between $(Na^+ + K^+)$ATPase inhibition and patient age, perhaps because we attempted to age-match normotensives and hypertensives. The absence of females from the hypertensive group precludes an evaluation of the role of sex. One of the previously diagnosed hypertensive patients was normotensive on the day of blood withdrawal (MAP = 91 mm Hg); plasma samples from this individual exhibited a low (<4%) $(Na^+ + K^+)$ATPase inhibition. We have not yet obtained samples from patients with secondary forms of hypertension, therefore we cannot comment on the applicability of this assay as a diagnostic tool to discriminate between essential hypertension and secondary hypertension.

The maximal inhibition observed in this study was 14%—this is an underestimation of the inhibition expected *in vivo* because the plasma samples were diluted twofold in our assay. It seems reasonable to conclude that the apparent inhibitory activity represents an effect on $(Na^+ + K^+)$ATPase *per se*, because the contribution of ouabain-insensitive Mg^{2+}-ATPase to the total steady-state hydrolysis of ATP is less than 2% in these conditions.

As our $(Na^+ + K^+)$ATPase preparation consisted of unsealed membrane sheets[9], we were unable to distinguish between an external and an internal site of action for the inhibitor. The data of Pamnani *et al.*[4] on experimental models of hypertension, and those of Poston *et al.*[3] on essential hypertension, indicate that the inhibitor acts at an external site, assuming (1) that the inhibitor does not cross the plasma membrane quickly, and (2) that our inhibitor is the same as theirs. Our kinetic data imply that the circulating inhibitor must bind much more rapidly than ouabain.

Figure 3 incorporates further data on red cell Na^+ levels and digoxin-like immunoreactivity in these plasma samples. The mean essential hypertensive MAP was more than two standard deviations above the mean normotensive MAP. Mean % inhibition of $(Na^+ + K^+)$ATPase was significantly elevated in the EH group, as was intracellular erythrocyte Na^+ content.

The plasma samples were tested for digoxin-like immunoreactivity, following the report of an endogenous digoxin-like material in the plasma of volume-expanded dogs[10] and hypertensive monkeys[11]. This substance has been postulated to be an endogenous ligand for the cardiac glycoside binding site of the Na^+ pump. The action of such a substance may therefore be related to inhibition of Na^+ transport and elevation of cellular Na^+ as described in essential hypertension[12,13]. However, as illustrated in Fig. 3, we were unable to demonstrate a significant elevation of digoxin-like immunoreactivity in the plasma samples that inhibited the $(Na^+ + K^+)$ATPase. Furthermore, there was no correlation between the two assays, which suggests that the $(Na^+ +$

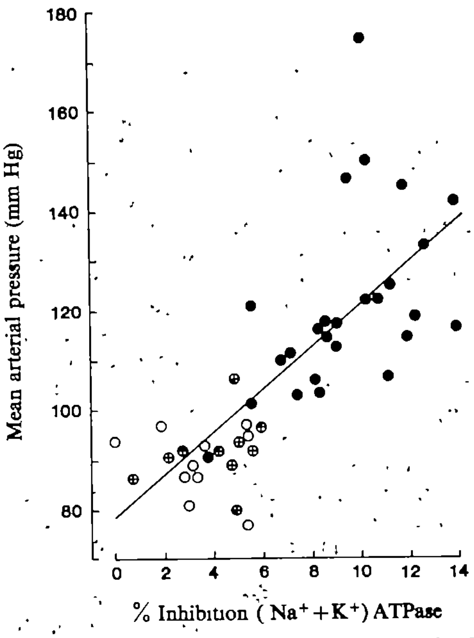

Fig. 2 Relationship between mean arterial blood pressure and inhibition of $(Na^+ + K^+)$ATPase by plasma samples from normotensive and hypertensive individuals; 20 normal subjects (age 34 ± 14 yr, range 21–66 yr) and 26 patients (age 49 ± 11 yr, range 32–67 yr) suffering from essential hypertension were studied. All the hypertensive subjects were males; 18 were black. Twelve of the normotensives were males, and six were black. None of the normotensives had known endocrine abnormalities, and none of the hypertensive patients showed any evidence of end-organ damage or serious intercurrent disease. All patients with essential hypertension had blood pressures higher than the 95th percentile for age and sex on at least three previous office visits, and had received no drugs for at least 2 weeks before the study. Thirty-six individuals, including all the patients with hypertension, were characterized endocrinologically using integrated hormone profiling based on the principle of continuous 6-h blood withdrawal[23,24]. The rationale for this collection protocol has been discussed elsewhere[23]. Plasma samples were collected continuously for 6-h periods using an indwelling non-thrombogenic catheter connected to a constant withdrawal pump. A sample (10 ml) was collected every 30 min into glass tubes containing (final concentrations) 2.8 mM EDTA, 3.4 mM EGTA and 2.6 mM glutathione on ice. Cells and plasma were separated by immediate centrifugation and the plasma was stored on ice. After the 6-h withdrawal, aliquots of the 30-min samples were combined to give a 6-h integrated pool. Plasma renin activity, aldosterone, cortisol, noradrenaline and adrenaline were measured as described elsewhere[23,24], no significant correlation was found between levels of these substances and blood pressure (data not shown). Systolic and diastolic blood pressures were measured at hourly intervals during blood collections, and the results were averaged. Mean arterial pressure was calculated as: MAP = 0.33 × pulse pressure + diastolic pressure. Plasma samples were analysed for Na^+ and K^+ (by flame photometry), inorganic phosphate[25] and protein content[26], and were stored at −20 °C. Plasma was subsequently deproteinized by acidification to pH 5.5 with 1.0 M HCl and boiled for 2 min. The resultant slurry was centrifuged at 30,000g for 30 min at 4 °C, and the clear supernatant removed for electrolyte and protein content determinations as before. The degree of protein removal was typically 99%, giving a final protein content of $800 \pm 180\ \mu g\ ml^{-1}$ in the supernatants. The deproteinized samples were then assayed for $(Na^+ + K^+)$ATPase inhibitory activity as described in Fig. 1*c* legend, and the remainder was lyophilized for use in the digoxin radioimmunoassay (RIA) (see Fig. 3). The order of assay samples was randomized to avoid bias. The average coefficient of variance for repeated estimations on the same samples was typically 1% or better. The final electrolyte composition of the assay cocktail varied because of the addition of plasma samples. Thus, the final assay conditions varied as follows. (in mM except as stated) K^+, 22–23; Na^+, 170–175; total Ca^{2+}, 3.25–4.5; free Ca^{2+}, $<10^{-7}$ M; total Mg^{2+}, 9.5–9.6; free Mg^{2+}, 2.1–2.8, total EGTA, 6.7; free EGTA, 2.2–100 μM; total EDTA, 1.4–2.1, free EDTA, $<10^{-8}$ M; total ATP, 3; free ATP, $<10^{-7}$ M; PO_4, 0.4–0.6. Surprisingly, we found that controlled variation of K^+ (20–30 mM), Na^+ (100–200 mM), free EGTA (1–500 μM), free Mg^{2+} (2–2.8 mM), and PO_4 (0.4–0.6 mM) gave no more than a 2% change in the steady-state activity of $(Na^+ + K^+)$ATPase. High concentrations ($>10^{-4}$ M) of free Ca^{2+} and ATP are both potent inhibitors of the ATPase but, due to the presence of excess EGTA and Mg^{2+}, respectively, they are reduced to non-interfering levels in our assay. In addition, the excess EGTA also serves to chelate other trace elements that may interfere with the assay. Given these and other considerations, we estimate that the cumulative error for each determination of ATPase activity was ~3%. This uncertainty and the variability of blood pressure could contribute to the scatter observed. ●, ⊕ Correspond to 6-h integrated samples collected from patients with essential hypertension and from normotensives, respectively. ○, Discrete single samples collected from normotensives. The regression line was fitted by the least-squares method; the correlation between MAP and % inhibition is highly significant ($r = 0.73, P < 0.0005$)

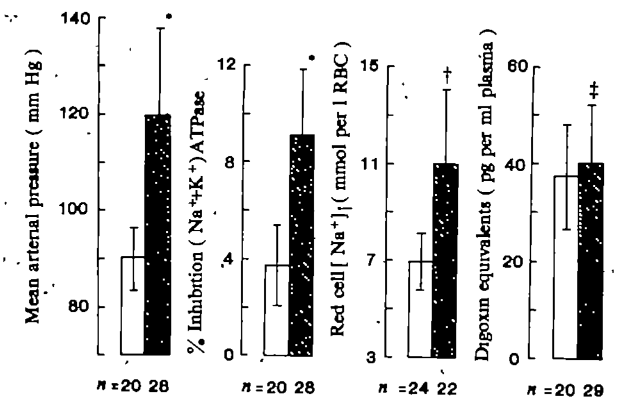

Fig. 3 MAP, % $(Na^+ + K^+)$ATPase inhibition, intracellular red blood cell (RBC) Na^+ content and plasma digoxin equivalents in normotensive (open bars) and hypertensive (cross-hatched bars) individuals. Determination of MAP and inhibition of $(Na^+ + K^+)$ATPase are described in Fig. 2 legend. Red cell Na^+ content was determined on freshly collected cells by atomic absorption spectroscopy after three washes of the cells in isotonic $MgCl_2$, determination of haematocrit and lysis of cells in deionized H_2O. Subsequent dilutions were performed in CsCl. For technical reasons, 34 of the red cell Na^+ determinations were performed on cells from individuals other than those tested for $(Na^+ + K^+)$ATPase inhibition and digoxin-like immunoreactivity However, all the blood samples were obtained from individuals in the same populations as those identified for study. Plasma digoxin equivalents were determined by digoxin RIA (NEN) essentially as described by Gruber *et al.*[10]. Deproteinized plasma samples were lyophilized and resuspended to 10× their original concentration in H_2O and assayed for their ability to compete with iodinated digoxin for a digoxin-specific antibody. Some samples were seeded with digoxin to ensure that the antibody was not affected by the increased electrolyte content of the assay. The data presented are corrected for concentration and dilution factors incurred during sample preparation, and are described as pg digoxin equivalents per ml plasma. None of the individuals had received cardiac glycosides. Values shown are mean±s.d. of the indicated number of samples. Significance of the differences in the means was determined by Student's *t*-test: $^*P < 0\ 0005$; $^\dagger P < 0.005$; ‡not significant ($P > 0.1$)

K^+)ATPase inhibitor we describe and the digoxin-like substance may not be related.

We have previously discussed the manner in which inhibition of Na^+ transport may lead to a rise in blood pressure[1,14,15]. Inhibition of Na^+ pumps in vasular tissue by ouabain results in increased resting tone[16] and enhanced reactivity to catecholamines[16]. As an increase in intracellular free Ca^{2+} is the immediate trigger for concentration in vascular smooth muscle[17], it seems reasonable to suppose that inhibition of Na^+ pumps leads to a net accumulation or redistribution of intracellular Ca^{2+}. This phenomenon may occur as a consequence of a Na^+–Ca^{2+} exchange mechanism at the vascular smooth muscle cell plasma membrane[1,14,15], whereby the increase in intracellular Na^+ by Na^+ pump inhibition leads to a net uptake of Ca^{2+} and, thus, to an increase in peripheral vascular resistance—the hallmark of the hypertensive process[18]. In addition, inhibition of Na^+ pumps in sympathetic nerve terminals may enhance catecholamine release[19] and reduce re-uptake[20], and thus contribute to the maintenance of elevated vascular smooth muscle tone[15].

The sequence of events leading to the elevated levels of $(Na^+ + K^+)$ATPase inhibitor in the plasma may be the result of a congenital (or, in some types of secondary hypertension, acquired) defect in the renal natriuretic capability in individuals prone to develop hypertension[21]. Excessive Na^+ ingestion by these individuals would result in Na^+ and water retention and the tendency towards expansion of the extracellular fluid volume unless adequate compensatory physiological mechanisms are brought into play. Our data support the view that one such compensatory mechanism may be increased secretion of an inhibitor of $(Na^+ + K^+)$ATPase that enhances Na^+ excretion (that is, a natriuretic hormone[22]). Increased circulating amounts of this substance may induce hypertension as a side effect[1]. In addition to their possible significance for pathophysiology, our observations imply that, even in normal circumstances, the activity of Na^+ pumps may be directly modulated *in vivo* by humoral substances.

We thank Professor H. E. deWardener, Professor G. G. Pinter and Dr W. J. Lederer for comments on the manuscript, and Ms M. Tate and A. Wilder for preparing the typescript. This research was supported by MDA, NSF, NINCDS and NICHHD. J.M.H. was supported by an AHA (Maryland Chapter) Fellowship.

Nonspecific inhibitor released by T acceptor cells reduces the production of interleukin-2

Miroslav Malkovsky*, Geoffrey L. Asherson*, Brigitte Stockinger† & Madeleine C. Watkins*

* Division of Immunological Medicine and † Transplantation Biology Section, Clinical Research Centre, Watford Road, Harrow, Middlesex HA1 3UJ, UK

Mice exposed to contact sensitizing agents such as oxazolone (ox) or picryl (pic) derivatives develop specific immunological suppression to these substances which results from the activation of a circuit of T suppressor cells[1–3]. However, one of the final immunological events in the T suppressor cell circuit is the release of a nonspecific, H–2 unrestricted inhibitor by I–J$^+$, Lyt-2$^+$ cyclophosphamide-sensitive T acceptor cells (Tacc)[3–7]. This nonspecific inhibitor (nsINH) can block the passive transfer of contact sensitivity and depress DNA synthesis by lymphocytes exposed to mitogens and alloantigens but the molecular mechanism is poorly understood. We provide evidence here that the production of interleukin-2 (IL-2)[8–15] by stimulated lymphoid cells is suppressed when the cells have been exposed to nsINH.

The T suppressor cell circuit, which has an important role in the modulation of immune responses to ox and pic derivatives, involves Lyt-1$^+$2$^+$ hapten-specific T suppressor cells producing hapten-specific T suppressor factor (TsF), which arms the Tacc; the armed Tacc population then liberates nsINH when exposed to hapten-modified (oxazolonated or picrylated) lymphoid cells corresponding in hapten specificity to TsF and bearing the same I–J subregion as the source of TsF[3–7]. Our initial observation was that nsINH diminishes proliferative responses to con-

0028–0836/82/500652—04$01 00

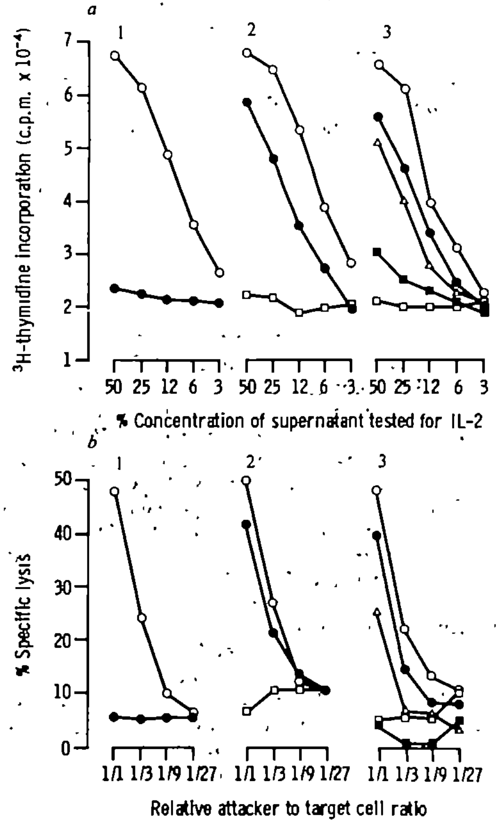

Fig. 1 Reduced IL-2 activity in supernatants of Con A-activated mouse spleen cells exposed to nsINH. A lymphoid cell suspension was prepared by pressing BALB/c spleens through a fine mesh screen into RPMI 1640 medium. Erythrocytes were lysed using Boyle's solution[27]. The lymphoid cells were mixed with various concentrations of the nsINH supernatant or with 100% of the control supernatants (10^7 cells ml^{-1}); Con A (5 μg ml^{-1}) was added and the suspension was distributed in 4-ml aliquots into 12-well flat bottom Linbro tissue culture plates (Flow). Similarly, 4-ml aliquots of the same cells (10^7 cells ml^{-1}) were resuspended in RPMI 1640 medium with (positive assay control) or without (negative assay control) Con A (5 μg ml^{-1}), and distributed into the plates. After 4 h incubation, the supernatant was carefully removed and discarded. Fresh serum-free RPMI 1640 medium (without Con A) was added and the supernatant was collected after a further incubation for 20 h and tested for IL-2 activity in two different assays. The presence of IL-2 was measured initially using 4 day Con A blast cells essentially following ref. 14 (Fig. 1*a*). BALB/c Con A blast cells (10^6 cells ml^{-1}) were cultured in 0.2 ml supplemented RPMI 1640 medium in the presence of various concentrations of the supernatants to be tested for IL-2 activity. Cultures were set up in quadruplicate in 96-well Titertek tissue culture plates. Five hours before collection, each well was pulsed with 1 μCi [*Me*-^{3}H]thymidine. The cultures were collected after 25 h and tritiated thymidine incorporation was determined. In *a*, the supernatants tested for the IL-2 activity were: panel 1: supernatant from untreated spleen cells, the negative assay control (●), supernatant from Con A-activated spleen cells, the positive assay control (○); panel 2: supernatants from Con A-activated spleen cells exposed to a 100% nsINH supernatant (□) or to 100% control supernatants prepared with the omission of either antigen (○) or TsF (●) (see Table 1); panel 3: supernatants from Con A-activated spleen cells exposed to different concentrations of the nsINH supernatant—50% (□), 25% (■), 12% (△), 6% (●), 3% (○). The abscissa indicates the concentration of the supernatants tested for IL-2. The ordinate indicates the IL-2 activity as measured by the tritiated thymidine incorporation by Con A blasts. Con A blasts incubated in culture medium only for 25 h incorporated tritiated thymidine to a similar extent as the negative assay control (19,555 ± 2,721 c.p.m.). In *b*, the same supernatants were assayed for IL-2 activity by their capacity to sustain the growth and function of cultured CTL[9,16]. The following modification of the original method described in ref. 16 was used. Female CBA (H-2^k) spleen cells from untreated mice (4×10^6 cells ml^{-1}) were co-cultured with irradiated (2,000 R, ^{60}Co source) NZB (H-2^d) stimulator lymphoid cells (2×10^6 cells ml^{-1}) in supplemented RPMI 1640 medium with 5×10^{-5} 2-mercaptoethanol. Cultures were seeded in 12-well flat bottom Linbro tissue culture plates in a total volume of 4 ml per well. After 5 days, dead cells were removed by centrifugation over Ficoll/Isopaque[28]. Live cells (0.25×10^6 cells per ml) were co-cultured with fresh irradiated NZB stimulator lymphoid cells (10^6 cells per ml) for another 2 days. The cells were then collected, purified over Isopaque/Ficoll[28] and plated in 24-well flat bottom Linbro tissue culture plates (Flow). Cells (2×10^4 cells ml^{-1}) were incubated in various concentrations of supernatants to be tested for the IL-2 activity or in culture medium for 3 days. For the cytotoxicity assay, the cells were washed once and resuspended in 0.5 ml supplemented RPMI 1640 medium; 0.1-ml triplicates of four threefold dilutions were set up in 96-well U-bottom Microtiter plates (Sterilin) and incubated in a total volume of 0.2 ml with P815 (H-2^d) target cells (3×10^3 cells per well) labelled with Na$_2$[^{51}Cr]O$_4$ (specific activity: 100–400 mCi per mg Cr, Amersham, UK). The Cr-release was stopped by centrifugation after 3 h incubation by centrifugation (300*g*, 10 min, 4 °C). The Cr-release c.p.m. were determined by counting a 100-μl supernatant from each well in a gamma counter.

$$\%\ \text{Specific lysis} = \frac{\text{experimental c.p.m.} - \text{medium control c.p.m.}}{\text{maximum release c.p.m.} - \text{medium control c.p.m.}} \times 100$$

Medium control c.p.m. were obtained from 100-μl supernatant aliquots taken from wells containing radiolabelled target cells only. Maximum release c.p.m. were obtained from wells containing radiolabelled target cells in 5% Triton X-100 (BDH). *b* Shows the cytotoxic potential of murine secondary CTL incubated for 3 days in the presence of a 25% concentration of the supernatants tested for the IL-2 activity and the panels are as in *a*. Relative attacker to target cell ratios are indicated on the abscissa and % specific lysis on the ordinate. Very similar results were obtained with other concentrations of the supernatants and the cytotoxic cells were shown to be T lymphocytes with monoclonal anti-Thy-1.2 antibody (Olac) and complement (unpublished data).

canavalin A (Con A) only when added less than 8 h after the proliferative stimulus[3,7]. However, the effect of nsINH could be overcome by adding exogenous IL-2 but not by increasing the concentration of Con A. These findings prompted investigation of the possibility that the effect of nsINH could be due to the relative lack of IL-2 in cultures of stimulated lymphoid cells which had been treated with nsINH. In the first set of experiments we prepared control supernatants and supernatants containing nsINH and tested them in the DNA synthesis assay (Table 1). The nsINH supernatant (50% concentration) of BALB/c origin depressed Con A-induced DNA synthesis to ~40% of the control value in syngeneic BALB/c (Table 1) or in allogeneic B10.A or CBA (data not shown) indicator cells, while control supernatants were inactive.

The second set of experiments examined the ability of nsINH supernatants to influence Con A-induced IL-2 production by lymphoid cells. BALB/c spleen cells were suspended in culture medium or in 100% control supernatants or in different concentrations of a supernatant with nsINH activity and exposed to Con A. After a 4-h incubation, the culture fluids were removed and replaced with serum-free RPMI 1640 medium. The production of IL-2 by the cells was assessed by measuring the IL-2 activity in the culture medium after a further 20-h incubation using both proliferation[14] and functional[9,16] assays for IL-2 (Fig. 1). The results, confirmed in seven independent experiments, showed that the production of IL-2 by stimulated lymphoid cells was at least 15-fold lower as estimated by the biological assays for IL-2, when the cells were exposed to 25–100% concentration of nsINH supernatant. Moreover, the action of nsINH was nonspecific and H-2-unrestricted and was not limited to Con A-induced IL-2 production. Table 2 shows that nsINH of BALB/c or CBA origin inhibited the production of IL-2 in supernatants from Con A- or alloantigen-stimulated BALB/c or CBA spleen cells.

Table 1 Nonspecific inhibitor depresses the DNA synthetic response to Con A in spleen cells

Preparation of supernatant Tacc (4-day ox spleen/lymph-node cells)	TsF (anti-picryl)	Antigen (picrylated spleen cells)	Additions to test culture	^{3}H-thymidine incorporation (c.p.m. ± s.d.)	% of Con A response
			—	57±10	
			Con A (2 μg ml^{-1})	45,800±379	100 (standard)
+	+	−	Con A+50% control supernatant (no antigen)	44,857±2,017	98
+	−	+	Con A+50% control supernatant (no TsF)	41,693±4,970	91
+	+	+	Con A+50% nsINH supernatant	17,489±341	38

The nsINH is released by Tacc armed with TsF and triggered by antigen[3–7]. Six to nine-week-old female BALB/c mice were used throughout. The anti-picryl T suppressor factor (pic TsF) was produced by 48-h cultures of lymphoid cells from mice injected and then painted with picryl derivatives[6,7,24]. The lymphoid cells (10^7 cells per ml) were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO$_2$ in supplemented RPMI 1640 medium (Flow). The supplemented RPMI 1640 medium contained 5% fetal calf serum (Flow), 2×10^{-3} M L-glutamine (Sigma), 1×10^{-3} M HEPES (Flow), 100 IU ml^{-1} penicillin and 100 μg ml^{-1} streptomycin (Glaxo). Nylon wool purified T cells[25] from spleen and lymph nodes taken 4 days after painting mice with oxazolone were used as the Tacc population[6,7]. The spleen cells were picrylated by the method of Shearer[26]. Control supernatants and supernatants containing nsINH were prepared following refs 6 and 7. In brief, the Tacc population was incubated in a supernatant containing pic TsF (25×10^6 cells per ml) for 1 h and shaken occasionally. The armed Tacc were recovered by centrifugation and mixed with a third of their number of picrylated cells, centrifuged, resuspended in supplemented RPMI 1640 medium (25×10^6 Tacc ml^{-1}) and incubated for 2.5 h. The suspension was centrifuged and the supernatant filtered through a 0.22-μm Millex-GS filter (Millipore). Control supernatants were prepared by omitting either picrylated cells or pic TsF. These supernatants were tested in the DNA synthesis assay[7]. Briefly, spleen cells from untreated mice (7.5×10^5 cells ml^{-1}) were cultured in 0.2 ml of supplemented RPMI 1640 medium with 2×10^{-5} M 2-mercaptoethanol (type I, Sigma) and 2 μg ml^{-1} Con A (Pharmacia). (The batch of fetal calf serum was selected to be nonmitogenic for mouse cells so that DNA synthesis in cultures untreated with mitogens was less than 2% of DNA synthesis in mitogen-treated cultures.) Cultures were set up in quadruplicate in 96-well Titertek tissue culture plates (Flow). The final concentration of supernatants in the assay was 50%. Five hours before collection, each well was pulsed with 0.5 μCi [*Me*-^{3}H]thymidine (specific activity: 5 Ci mM^{-1}, Cat. no. TRA.120, Amersham). The plates were collected after 72 h using a multicell cell collector (Scatron) and Titertek collector filters (Flow). Tritiated thymidine incorporation was determined by liquid scintillation counting in 2 ml Micellar Scintillator (Nuclear Enterprises).

It was possible that nsINH might act indirectly by inducing the release of an IL-2 inhibitor[17], which could block the action of IL-2. To exclude this possibility, the IL-2 supernatant (the positive assay control in Fig. 1) and the supernatant from Con A-activated spleen cells exposed to nsINH were subject to preparative isoelectric focusing (Fig. 2). In the control supernatant, the IL-2 activity was recovered as a single peak in the *p*H range of 3.8 to 4.6; peak activity migrated with an isoelectric point of 4.1 in keeping with ref. 14. The results of Watson *et al.*[18], who reported two distinct peaks (*p*I 4.3 and 4.9) of murine IL-2 activity, may reflect the known heterogeneity of IL-2 which is due in part to variable glycosylation. However, no IL-2 activity was recovered from the supernatant from Con A-activated cells exposed to nsINH. Moreover, the data in Table 3 show that inactive supernatant did not affect the ability of IL-2 to promote cell proliferation. It was concluded that nsINH reduced the production of IL-2 by lymphoid cells and did not induce an inhibitor of the action of IL-2. The nsINH was not nonspecifically toxic to lymphoid cells because the cell viability assessed by trypan blue dye exclusion of normal unstimulated spleen cells was unaffected by the presence of nsINH. Moreover, the growth of lymphoid cell lines BW 5147 (ref. 19), EL4 (ref. 20) and P3-NSI/1-Ag4-1 (ref. 21) was not influenced by nsINH. Finally, nsINH had no effect on Con A-induced cell proliferation when added after the first 8 h of culture[3,7] and its effect when added at the beginning of culture was abolished by exogenous IL-2. For instance, in an experiment in which spleen cells, stimulated by Con A, incorporated 94,963±8,174 c.p.m. of tritiated thymidine on day 3, but only 25,771±3,325 c.p.m. in the presence of 50% nsINH, cell proliferation was completely restored (96,008±7,027 c.p.m.) by adding 20% supernatant containing exogenous IL-2.

Preliminary data suggested that the nsINH, which had an isoelectric point of 6.4–6.9 and a molecular weight of 40–60,000, did not influence the differentiation of primary or secondary cytotoxic T lymphocytes (CTL)[3,7]. These data are compatible with the view that a distinct soluble factor but little or no IL-2 are required to induce differentiation of effector CTL from resting precursors[22,23]. The present T suppressor cell circuit[3–7] involving the liberation of nonspecific inhibitor of the

Table 2 The action of nonspecific inhibitor is not H-2-restricted

	IL-2 assay (c.p.m. ± s.d.)		
		Nonspecific inhibitor present (50% v/v) Origin of the nonspecific inhibitor	
Origin of IL-2	Nonspecific inhibitor absent	BALB/c	CBA
Alloantigen-stimulated BALB/c	27,211±3,185	5,824±795	5,762±823
Con A-stimulated BALB/c	45,895±3,455	5,956±1,491	6,167±1,002
Alloantigen-stimulated CBA	29,286±1,920	5,837±921	5,626±813
Con A-stimulated CBA	49,186±3,696	6,170±504	5,844±879

Mixed lymphocyte cultures were set up as described elsewhere[7]. In brief, BALB/c or CBA spleen cells at a final concentration of 5×10^6 cells ml^{-1} were co-cultured with equal numbers of irradiated (2,000 R, ^{60}Co source) allogeneic stimulator CBA or BALB/c spleen cells in the absence or presence of nsINH. After a 3-day incubation, the supernatant was removed and replaced with fresh culture medium, which was collected after a further 1 day incubation and tested for IL-2 activity. The preparation of supernatants from Con A-stimulated spleen cell cultures and the testing of the IL-2 activity of the supernatants by their capacity to promote the proliferation of 4-day Con A blasts are described in the legend to Fig. 1. The data in Table 2 show IL-2 production as measured by the proliferation of 4-day Con A blasts incubated for 25 h in the presence of a 25% concentration of supernatant. Similar results were obtained with other concentrations (50, 12, 6%) of the supernatants. The incorporation of tritiated thymidine into Con A blasts incubated for 25 h in culture medium only was 5,407±807 c.p.m. Alloantigen- or Con A-stimulated cells liberated approximately the same amounts of IL-2 as the same cells exposed to control supernatants prepared with the omission of either antigen of TsF (data not shown).

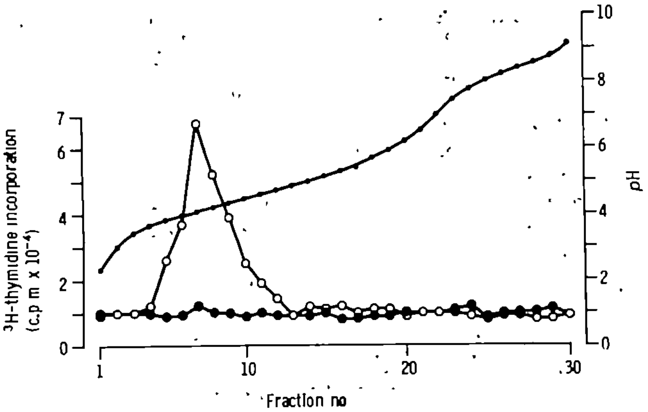

Fig. 2 IL-2 cannot be isolated by preparative isoelectric focusing from supernatants of Con A-activated spleen cell exposed to nsINH. Preparative isoelectric focusing was carried out in a flat-bed of Ultradex gel (LKB) using the LKB 2117 Multiphor Apparatus following refs 14 and 18. Briefly, a final concentration of 4% Pharmalyte ampholites (pH 3–10, Pharmacia) was added to samples, which were electrophoresed for 16 h at a constant power of 8 W. The gel was then sectioned into 30 slices, each slice was eluted with 2 ml H_2O and the pH was determined. Each sample was dialysed against phosphate-buffered saline, finally against RPMI 1640 medium and assayed for biological activity using Con A blast cells as described in Fig. 1 legend. The supernatants were from Con A-activated spleen cells (○) and from Con A-activated spleen cells exposed to a 100% supernatant containing nsINH (●). The pH curve is given for the supernatant from Con A-activated spleen cells. Fractions 4–15 of the second supernatant had the same pH and the difference between the pH of corresponding samples of remaining fractions was less than 0.2.

Table 3 Absence of an inhibitor of the action of IL-2 in a supernatant from Con A-activated spleen cells exposed to nsINH

Additions to test culture	^{3}H-thymidine incorporation (c.p.m. ± s.d.) Medium	Supernatant
—	7,624±230	7,508±1,933
5% IL-2	21,001±1,600	20,589±763
10% IL-2	42,481±1,885	42,230±1,089
20% IL-2	57,381±2,779	55,692±1,207
30% IL-2	64,607±4,577	63,792±7,345
40% IL-2	79,773±2,834	77,865±774

Various final concentrations of an IL-2 supernatant (the positive control in the experiment described in Fig. 1) were prepared by diluting in either RPMI 1640 medium or in a supernatant, from Con A-activated spleen cells exposed to a 100% supernatant containing nsINH, in which IL-2 activity could not be detected directly (Fig. 1) or after preparative isoelectric focusing (Fig. 2). The dilutions were assayed for IL-2 activity by their capacity to promote the proliferation of 4-day Con A blasts using the technique described in the legend to Fig. 1.

production of IL-2 could provide a mechanism which limits the entry of new cells proliferating under the action of IL-2 into an immune response.

This work was supported by the Wellcome Trust and the Deutsche Forschungsgemeinschaft. We thank Dr Elizabeth Simpson for providing the P815 tumour cell line and for stimulating discussions and Dr Malcolm Brenner for valuable suggestions.

Influenza A specific cytotoxic T-cell clones that do not recognize viral glycoproteins

A. R. M. Townsend* & J. J. Skehel†

Since the demonstration that murine cytotoxic T cells generated during a secondary immune response to influenza A viruses were composed of cross-reactive and subtype-specific populations[1–6], it has become of interest to define the viral components responsible for each pattern of recognition. One approach is by the isolation of individual clones of cytotoxic T cells[6,7] which can then be tested for recognition of natural or laboratory-induced virus variants of known genetic composition. We describe here a series of influenza A virus subtype-specific clones raised against the recombinant X31(H3N2)[8] virus, which contains the haemagglutinin (HA) and neuraminidase (NA) from the 1968 virus, and all its remaining genes from the 1934 virus[9]. We show here that the viral gene responsible for the determinant recognized by these cytotoxic T-cell clones codes for neither the haemagglutinin nor neuraminidase glycoproteins, that it segregates independently of HA and NA during the formation of recombinant viruses, and that it undergoes independent genetic change.

The virus X31 (H3N2) is a recombinant between A/Aichi/1968 (H3N2) and A/PR/8/1934 (H1N1). Clones able to recognize the recombinant virus X31 (H3N2) but not A/USSR/90/77 (H1N1)-infected target cells are here called subtype-specific. The subtype-specific cytotoxic clones examined here all show either no or very little activity on A/USSR compared with X31, and were selected on this basis for closer inspection. In each experiment a cross-reactive clone, T6-11-5-1, or polyclonal line D, able to kill targets infected with any influenza A virus, served as a positive control, as different viruses tend to infect target cells with varying efficiency.

Figure 1 shows the spectrum of activity of clone A3.1. It reveals that target cells infected with A/PR/8/1934 are recognized but that A/Aichi/1968 is not, while the cross-reactive control kills both equally well. As A/PR/8/1934 contributes all the genes to X31 other than the HA and NA genes[9], the subtype-specific component being recognized seems not to be the haemagglutinin or neuraminidase surface glycoproteins. Figure 1 also shows that the virus component recognized underwent genetic change between 1943 and 1946 because the 1943 virus infected cells are killed as efficiently by A3.1 as by the cross-reactive control, whereas the 1946 and 1947 virus infected targets are not killed at all by A3.1 but are killed very efficiently by the cross-reactive control. The influenza B/Hong Kong/8/73 infected target acts as a specificity control for both cross-reactive and subtype-specific populations. Four other clones (three from a separate culture), derived in the same way as A3.1, showed the same pattern (Table 1), killing A/PR/8/1934 targets but not A/Eng/42/1972 targets (which is antigenically similar to A/Aichi/1968).

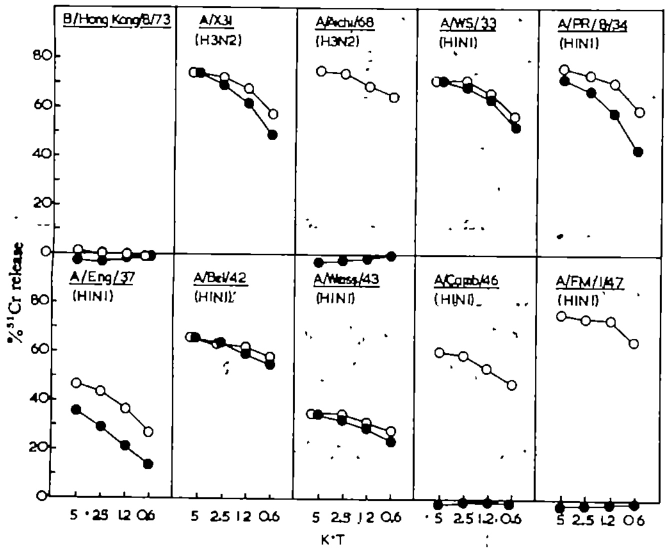

Fig. 1 Spectrum of activity of clone A3.1 on target cells infected with various influenza A viruses (●—●); line D effectors (○—○) act as cross-reactive control. Combined results from two experiments. T-cell clones: the derivation and maintenance of clone A3.1 and clones depicted in the other figures will be described in detail elsewhere (A.R.M.T. and P. M. Taylor, manuscript in preparation). Briefly, polyclonal cytotoxic lines were established by repeated stimulation *in vitro* of spleen cells from intranasally primed donor mice with X31 infected, irradiated, syngeneic spleen cells. After two stimulations growth factors were added each time as 20% v/v supernatant from concanavalin A pulsed rat spleen cells (CAPS/N). After at least two more stimulations *in vitro*, the cells were cloned by limiting dilution at least once at 0.5 cells per well onto an X31 infected syngeneic spleen cell feeder layer. Growing clones were transferred to 2-ml Costar wells after 7–14 days and maintained in Costars by stimulation every 3–5 days in the presence of 20% CAPS/N. The subtype-specific clones originated from X31 primed mice and were selected and maintained using X31 *in vitro*. Clones A3.1 and A3.6-5.4 were derived from the same cell line, B10.7, B8.3 and C2.2 from a different line. The cross-reactive control clone T6–11-5-1 and the polyclonal line D were derived from A/JAP/305/57 (H2N2) primed mice and were selected by X31 *in vitro*. All cells were grown in RPMI/1640 medium supplemented with 10% fetal calf serum, penicillin, streptomycin, glutamine and 5×10^{-5}M 2-mercaptoethanol. All the subtype-specific clones described show *H–2* restricted recognition, requiring the class I molecule D^b on the target cell surface[24]. The cytotoxicity assay was performed as described previously[24]. Cloned cytotoxic T cells were incubated, at the ratios indicated, with ^{51}Cr-labelled target cells infected with the test virus (50–400 μl infectious allantoic fluid per 10^7 cells per 90 min) in a 6-h assay. The per cent specific ^{51}Cr released from lysed target cells was calculated as follows:

$$\frac{\text{(Release in presence of cytotoxic T cells} - \text{medium release)}}{\text{(Triton release} - \text{medium release)}}\times 100$$

All points measured in duplicate where four different killer : target ratios (K : T) were tested or quadruplicate where 1K : T was tested. Target cells were EL4 cells maintained as an ascitic tumour *in vivo*. Spontaneous ^{51}Cr release in presence of medium (SR) = 13–34%.

One clone, A3.6-5.4, from the same culture as A3.1, was tested on a number of viruses of the H3N2 subtype isolated between 1968 and 1979 (Fig. 2). It was unable to kill targets infected with any of them, whereas the cross-reactive clone T6-11-5-1 was positive on all the A virus infected targets.

To be sure that the determinant from the 1934 virus being recognized was encoded by a gene other than HA or NA, we tested clones on targets infected with a variety of recombinant viruses produced by crossing post-1968 H3N2 viruses with either A/PR/8/1934 (H1N1) or A/Bel/1942 (H1N1) (Fig. 3). Of these X31, MRC11 and X47 are antigenically H3N2, MRC1 and Mem/Bel 102 are H3N1. As illustrated by clone A3-6-5-4 (Fig. 3) the X31 and MRC1 infected targets are killed, but not the MRC11, Memphis/Bel 102, or X47 targets, whereas the cross-reactive control kills all the targets infected with recombinant A viruses.

We have found that polyclonal cytotoxic T-cell lines originating from C57B/6 mice primed with X31 and maintained *in vitro* by stimulation with X31, initially show characteristic cross-reaction on all influenza A virus-infected targets[1], but after several stimulations give rise to subtype-specific clones with high frequency (data not shown). There is thus, in the C57B/6 strain at least, a selection *in vitro* for the A virus subtype specific subset using this protocol. The clones discussed here are from such an *in vitro* selected population.

Previously, attention has naturally focused on the haemagglutinin molecule as a source of virus subtype-specific determinants recognized by B (refs 10, 11) and T cells[12], the more so because it has been shown by several workers that secondary cytotoxic T-cell responses induced *in vitro* with purified viral haemagglutinin show subtype-specificity, and the determinants responsible map to the HA gene when tested on appropriate recombinant viruses[2,13]. Haemagglutinin-specific cytotoxic T cells must therefore exist.

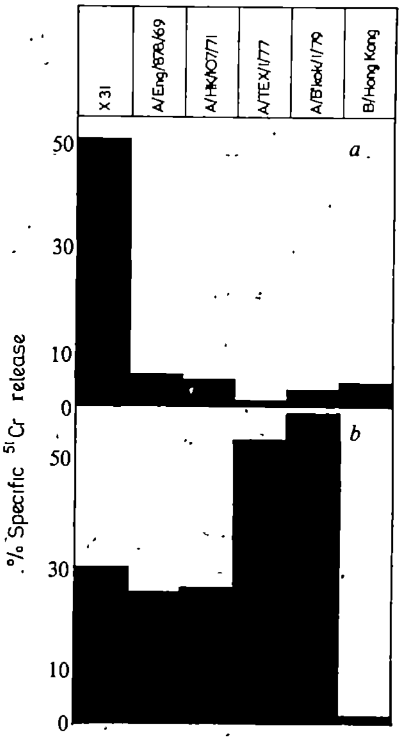

Fig. 2 *a*, Activity of clone A3.6-5.4 on target cells infected with post-1968 H3N2 influenza A viruses. *b*, Cross-reactive control clone T6-11-5-1. Combined results from two experiments. Thioglycollate induced PEC as targets. SR = 25–42%.

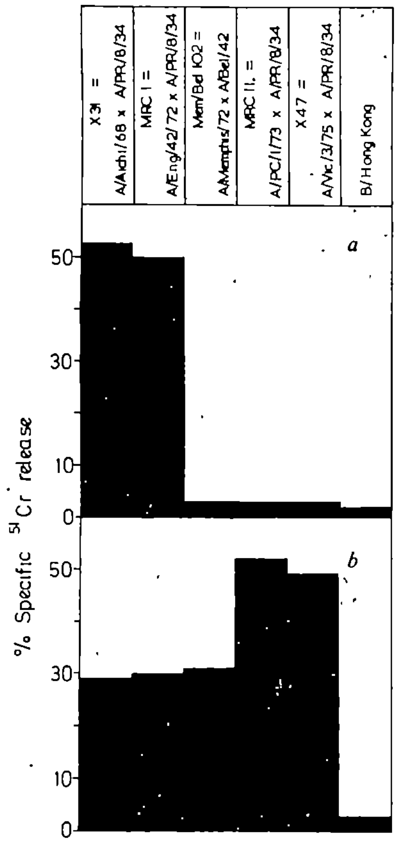

Fig. 3 *a*, Activity of clone A3.6-5.4 on recombinant viruses. *b*, Cross-reactive control clone T6-11-5-1. Combined results from two experiments. Thioglycollate induced PEC as targets. SR = 19–52%.

It was thus a surprise to find that all the T-cell clones isolated by us in the way described (see Fig. 1 legend) do not recognize either of the viral surface glycoproteins. The evidence for this is twofold. First, of the two viruses which contribute genes to X31, only the A/PR/8/1934 is recognized despite the fact that X31 does not receive its HA and NA genes from A/PR/8/1934. Second, when tested on a variety of recombinant viruses of known surface glycoprotein constitution, X31 (H3N2) and MRC1 (H3N1) are killed, but Mem/Bel 102 (H3N1), MRC11 (H3N2) and X47 (H3N2) are not (Fig. 3), showing that the viral gene responsible for recognition of infected target cells by clone A3.6-5.4 can segregate independently of the HA and NA genes during the formation of these five different recombinant viruses.

Braciale *et al.*[7] describe a series of murine cytotoxic T-cell clones derived using a related protocol with A/JAP/305/1957 (H2N2) virus. A similarly high frequency of clones showed subtype specificity, and these could be dvided into those able to recognize targets infected only with 1957 H2N2 virus and those able to recognize both the 1957 and 1967 H2N2 viruses. Representatives of both groups when tested on recombinant viruses of known HA and NA composition seemed to be HA specific. However, it is possible that a non-HA gene responsible for recognition could have segregated by chance with the HA gene in the two recombinant viruses tested with a probability of 1/4.

Table 1 Activity of T-cell clones on target cells infected with different influenza A viruses

Clone	Virus K:T	% Specific ^{51}Cr release			
		X31	A/Eng/42/72	A/PR/8/34	B/Hong Kong
A.31	2..5	46	4	30	1
A3.6-5.4	2.5	53	2	30	2
B8.3	2.5	46	3	26	2
B10.7	2.5	45	2	27	1
C2.2	2.5	37	3	16	1
T6-11-5-1 Control	3	29	30	16	2

Thioglycollate-induced peritoneal exudate cells (PEC) used as targets. SR = 16–43%.

Lamb *et al.*[14] have described six human H3N2 influenza-subtype specific T-cell clones. All six gave a specific proliferative response only with either purified viral HA or NA, whereas five cross-reactive clones gave specific responses only with purified matrix protein (M) or nucleoprotein (NP). This result may, like our own, reflect the technique of *in vitro* selection used, and does not rule out subtype-specific determinants on viral components other than HA and NA.

The determinant we have defined with clone A3.1 undergoes genetic change, as shown in Fig. 1, between the 1943 and 1946 virus isolates. It is of interest that the timing of this change coincides with a major change in the antigenicity of the H1N1 nucleoprotein as shown by van Wyke *et al.*[15] using monoclonal antibodies and Schild *et al.*[16] using rabbit antisera to purified NP. Furthermore Schild *et al.*[17] identified the origins of the NP in X31, X47 and MRC11, three of the recombinants we used. X31 is the only virus to receive the A/PR/8/1934 NP gene, and the only one of these three recognized by clone A3.6-5.4. However, from the results presented here none of the virus proteins other than the HA and NA glycoproteins can be excluded as the target for these clones. Also, although NP has been shown to be expressed on the surface of infected cells[18,19], there are also reports that NS1[20] and M protein[21] can be detected on the surface of infected cells, albeit for the latter in very low quantities when compared with HA[22].

A recent report[23] implicates the polymerase 3 gene as an absolute requirement for recognition by an isolated subtype-specific cytotoxic T-cell clone. This clone was derived by stimulation with A/PR/8/1934, and the recombinant A virus recognition data conclusively showed that neither the HA nor NA genes from A/PR/8/1934 were required. Thus far it resembles clone A3.1; however, the former recognized only targets infected with 1934 and 1935 H1N1 viruses, while clone A3.1 recognizes all H1N1 viruses isolated between 1933 and 1943. The determinants detected by these two A virus subtype-specific clones may therefore be different.

A.R.M.T. is grateful for support by an MRC Training Fellowship.

Haemagglutinin of influenza virus expressed from a cloned gene promotes membrane fusion

Judy White*, Ari Helenius* & Mary-Jane Gething†

Enveloped animal viruses enter and infect cells by a process involving fusion of the viral membrane with a cellular membrane. In some cases (for example, Sendai virus[1]), the fusion event occurs at the plasma membrane; for many other viruses including influenza, entry occurs through the membranes of intracellular vesicles such as endosomes or lysosomes, where the fusion is triggered by the endogenous low *p*H[2–6]. This *p*H-dependent fusion activity has been studied *in vitro* using as targets cultured cells[7–9], erythrocytes[9,10] and liposomes[11–13]. Fusion is a function of the viral surface glycoproteins[12] and occurs at a threshold *p*H that is characteristic of each virus species and strain[8]. In the case of influenza virus, there is strong evidence that the haemagglutinin glycoprotein has a key role in both virus infectivity and fusion activity[9,12,14–16]. Both processes require a post-translational proteolytic cleavage of the haemagglutinin precursor, HA0, into the active form of the molecule, HA, which consists of two disulphide-bonded subunits, HA1 and HA2[17,18]. A new N-terminus is generated on the HA2 subunit, the C-terminus of which is embedded in the virus membrane[19]. At the low *p*H values required for fusion the cleaved HA undergoes a conformational change exposing this previously buried hydrophobic N-terminus of HA2[20], possibly enabling it to interact with the target membrane. While it has been established that HA is necessary for fusion, it is unclear whether HA alone is sufficient or whether other viral proteins are involved[21]. Here we use cells expressing HA from a cloned copy of the HA gene inserted into a recombinant simian virus 40 (SV40) vector[22] to demonstrate that the HA molecule displays fusion in the absence of any other influenza virus-encoded components. These results open the possibility of using HA-mediated membrane fusion as a system to deliver foreign molecules into mammalian cells.

Simian CV-1 cells infected with a recombinant SV40 virus (SVEHA3) which contains the HA gene from the Japan strain of influenza virus (A/Japan/305/57) express at the cell surface large quantities of a HA glycoprotein that is indistinguishable in its antigenic, physical and biological properties from authentic influenza viral HA0[22]. Figure 1 shows that it is possible to cleave the HA0 into HA1 and HA2 subunits by briefly treating the cells with a low concentration of trypsin.

Table 1 Comparison of the *p*H dependence of fusion of CV-1 cells by SV40-HA recombinant viruses and influenza virus

Virus	Trypsin	*p*H 6.0	5.5	5.3	5.1	4.9
SVEHA3	−	−	−	−	−	−
	+	−	−	+/−	+	+
SVEHA20-A$^-$ (anchor minus)	−	−	−	−	−	−
	+	−	−	−	−	−
SV40	−	−	−	−	−	−
	+	−	−	−	−	−
Mock	−	−	−	−	−	−
	+	−	−	−	−	−
Influenza (Japan)	−	−	−	−	−	−
	+	−	−	+/−	+	+
FFWO with influenza (Japan)	−	−	−	+/−	+	+

CV-1 cells were infected with the various viruses as described previously[22]. 24 h later the *p*H dependence of fusion of the cells was assayed, with or without prior treatment with trypsin, by the protocol described in Fig. 2 legend using FM adjusted to the indicated *p*H. The assay for fusion-from-without (FFWO) was performed as described previously[8] using both CV-1 and BHK cells as targets. − Indicates that no fused cells were observed, + indicates that all of the cell nuclei were present in polykaryons and +/− indicates that some but not all nuclei were present in polykaryons.

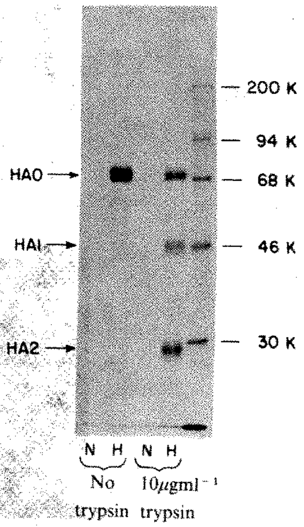

Fig. 1 Proteolytic cleavage of HA0 on the surface of SVEHA3-infected CV-1 cells. CV-1 cells were infected with SVEHA3 as described previously[22]. 48 h later the cells were labelled for 1 h with ^{35}S-methionine and then washed twice with serum-free medium. Medium containing 10 μg ml^{-1} trypsin (or lacking trypsin as control) was added to the monolayers which were then incubated for 15 min at 37 °C. Cell extracts were prepared, immunoprecipitated and analysed by SDS-polyacrylamide gel electrophoresis as previously described[22]. Autoradiography was for 12 h. N, normal rabbit serum; H, rabbit anti-HA serum. Molecular weight markers are indicated on the right.

Monolayers of CV-1 cells were infected with SVEHA3 to obtain expression of HA0 at their surface. When treated with trypsin and briefly exposed to *p*H 5.0, the cells fused to form giant polykaryons (Fig. 2*a*). This fusion was observed from 24 h post-infection, when the cells contained ~10^7 HA0 molecules, until just before cell lysis, which occurred at about 72 h post-infection when the cells contained ~10^9 molecules of HA0[22]. No fusion occurred unless either the infected cells were exposed to low *p*H (Fig. 2*b*, *d*) or the trypsin treatment was omitted (Fig. 2*c*, *d*). CV-1 cells that had been mock-infected or infected with wild-type SV40 did not fuse (Table 1). Thus, the HA expressed from the SV40-HA vector if activated by cleavage into HA1 and HA2 subunits, is capable of inducing low *p*H-dependent membrane fusion in the absence of other influenza viral components.

The *p*H dependence of the cell–cell fusion in SVEHA3-infected cells is virtually identical to that observed for fusion of influenza-infected CV-1 cells or for fusion-from-without of CV-1 or BHK cells by intact Japan virus (Table 1). Thus, the membrane environment in which the HA is anchored (the plasma membrane of cultured cells or the viral membrane) has little or no effect on the *p*H threshold for fusion. This is consistent with the observation of Skehel *et al.*[20] that the conformational change in isolated HA occurs at the same *p*H as does activation of fusion by the intact influenza virus[8].

Having established that the HA is necessary and sufficient for *p*H-dependent fusion, tests were performed to determine whether the protein had to be anchored to a membrane. The HA can be obtained, free of lipid and detergent, in three water-soluble forms: (1) as rosettes or protein micelles, in which the HA molecules are joined through their hydrophobic tails[23], (2) as free glycoprotein molecules, released from the virus membrane by digestion with bromelain (BHA)[24], and (3) as glycoprotein secreted from CV-1 cells infected with a recombinant vector (SVEHA20-A$^-$) containing a modified HA gene that lacks the DNA sequences coding for the C-terminal hydrophobic anchor (see accompanying paper[25]). The addition of HA rosettes or BHA spikes to monolayers of BHK cells did not cause any *p*H-dependent cell–cell fusion despite the fact that these cells could be completely fused from without by intact virions containing 50-fold less HA protein[8]. Furthermore, no fusion occurred when CV-1 cells infected with the anchor-minus mutant were treated with trypsin and exposed to low *p*H (Table 1). These results indicate that HA must be attached to a lipid matrix such as the viral envelope or the plasma membrane for fusion to take place.

0028–0836/82/500658—02$01.00

It has long been known that HA is responsible for binding influenza virions to cell-surface receptors[26]. More recently, it has become apparent that HA has a second major role in virus entry—that of fusion of the virus membrane with the membrane of endocytic vacuoles or lysosomes[2]. We have demonstrated that a HA produced from a cloned DNA copy of the RNA gene not only expresses the binding function[22], but also displays the *p*H-dependent fusion activity. These results show that no other influenza virus gene product is required for either of these functions. The binding and fusion activities, although carried out by the same protein, occur independently of each other. Fusion does not require sialic acid receptors in the target membrane[11,13] and binding to such receptors does not require the cleaved form of the HA that is obligatory for fusion[22]. Examination of the three-dimensional structure of the HA molecule[27] indicates that the two functions are separated into different physical domains of the protein. The proposed receptor binding sites are located at the tips of the spikes while the hydrophobic N-terminus of HA2, which becomes exposed at low *p*H (ref. 20 and J. J. Skehel, unpublished) and which has been implicated as the 'fusion peptide'[27–30], is found in the stem region at the base of the molecule close to where HA is anchored to the membrane.

The requirements for HA-mediated membrane fusion are (1) that the molecule be cleaved into its active form, (2) that it be anchored via its C-terminus into a lipid bilayer and (3) that it be exposed to low *p*H. A plausible mechanism satisfying these requirements and incorporating previous hypotheses[27–30] involves the two hydrophobic regions of the protein: one of these at the C-terminus anchors the protein into the membrane of the virus (or the infected cell); the second hydrophobic peptide at the N-terminus of HA2 is exposed by the conformational change at low *p*H and inserts into the target membrane. This conformational change cannot occur unless the protein has been cleaved. The HA protein now forms a bridge between the two membranes, bringing the lipid bilayers into close apposition and thus facilitating their fusion. Confirmation of this model and elucidation of the precise molecular details of the mechanism will require further studies. The feasibility of introducing mutations into the cloned copy of the HA gene, of reinserting the mutant genes into SV40-HA vectors and testing their effects on fusion activity after expression in CV-1 cells will allow definition of specific amino acids which participate in the fusion reaction.

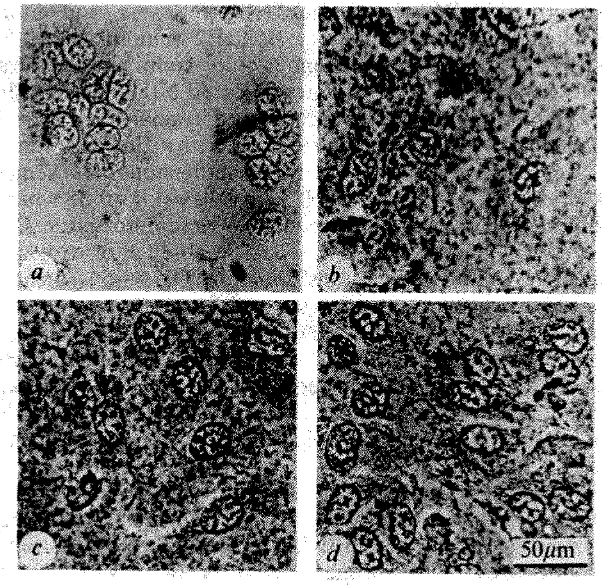

Fig. 2 Low *p*H-induced fusion of CV-1 cells expressing the HA of influenza virus. Confluent monolayers of CV-1 cells were infected with SVEHA3 as described previously[22]. 24 h post-infection, the cells were washed twice with serum-free Dulbecco's modified Eagle's medium (DMEM) and then incubated for 15 min at 37 °C in this medium (*c*, *d*) or medium supplemented with 10 μg ml^{-1} trypsin (*a*, *b*). The cells were then washed twice with DMEM plus 10% serum and then treated for 2 min at 37 °C with fusion medium (FM) (RPMI without bicarbonate, 0.2% bovine serum albumin, 10 mM MES, 10 mM HEPES) adjusted to either *p*H 5 (*a*, *c*) or *p*H 7 (*b*, *d*). These media were then replaced with DMEM containing 2% serum and the cells placed back at 37 °C for an additional 3 h. At this time they were fixed and stained with Giemsa as described previously[8]. Photomicrographs were taken with an Olympus PM-6 camera attached to an Olympus inverted phase microscope using Pan X film.

Finally, because of its binding and fusion capacities, the HA protein may be ideally suited to facilitate the efficient delivery of foreign substances into cells. Model studies aimed at developing liposome delivery methods can be carried out using cells expressing large amounts of HA from SV40-HA vectors. Preliminary results indicate that erythrocytes can be fused into such cells.

Activation of a cellular transforming gene in tumours induced by Abelson murine leukaemia virus

Mary-Ann Lane, Dorothy Neary & Geoffrey M. Cooper

Sidney Farber Cancer Institute and Department of Pathology,
Harvard Medical School, Boston, Massachusetts 02115, USA

Abelson murine leukaemia virus (AbMuLV) is an acutely transforming retrovirus which induces lymphoid neoplasms in mice with latent periods of 3–5 weeks[1]. The oncogenicity of AbMuLV is attributed to expression of a viral transforming gene (v-*abl*) which encodes a protein with tyrosine-specific kinase activity[2]. Two recent findings, however, suggest that oncogenesis by AbMuLV may not be a single-step consequence of v-*abl* expression. First, Whitlock and Witte[3] observed that AbMuLV infection of bone marrow cells *in vitro* stimulated proliferation of immature blast cells which did not exhibit the *in vitro* growth properties or tumorigenicity characteristic of cells from AbMuLV-induced neoplasms. These AbMuLV-infected cell populations evolved to fully neoplastic cells only

after several weeks in culture, suggesting that secondary events were required for expression of the neoplastic phenotype[3]. Second, Grunwald *et al.*[4] reported the loss of the AbMuLV genome after prolonged *in vivo* passage of some AbMuLV-induced neoplasms, suggesting that expression of v-*abl* may be necessary for initiation, but not maintenance, of transformation. We report here that AbMuLV-induced neoplasms contain cellular transforming genes detectable by transfection which are distinct from AbMuLV sequences. Taken together, these results suggest that v-*abl* expression may induce early events in the neoplastic process and that secondary activation of a distinct cellular transforming gene may be involved in progression to neoplasia.

DNAs used as donors in transfection assays were extracted from two cell lines, B6T1E2 and B6T4E4, derived from early (fifth) *in vivo* passages of neoplasms induced by injection of newborn C57BL/6 mice with AbMuLV[4]. These tumour cell lines contain exogenously integrated AbMuLV DNA, express the v-*abl*-encoded transforming protein p160, and exhibit phenotypic markers (Thy-1-negative, Lyt-1-negative, Lyt-2 negative, immunoglobulin-negative, DNL1.9-positive[5] and 14.8-positive[6]) characteristic of AbMuLV-induced pre-B-lymphocytic neoplasms (ref. 4 and R. Risser, personal communication).

B6T1E2 and B6T4E4 DNAs induced transformation of NIH 3T3 cells with high efficiencies (approximately 1 transformant per μg DNA; Table 1). These transforming efficiencies are comparable to those obtained with DNAs of other human or mouse lymphoid neoplasms[7], but are at least 200-fold higher than the transforming efficiency of normal cell DNAs. Several foci of NIH cells transformed by each tumour DNA were grown to mass culture for further study. DNAs of these transformed NIH cells induced transformation in secondary transfection assays with efficiencies comparable to those obtained with the primary tumour DNAs (see Table 1). These results indicate that AbMuLV-induced neoplasms contain activated transforming genes which can be detected and serially passaged by transfection of NIH 3T3 cells.

The content of AbMuLV DNA in NIH cells transformed by these tumour DNAs was investigated by restriction endonuclease digestion and blot hybridization using a v-*abl*-specific fragment of a cloned AbMuLV provirus (λAM-1)[8] as probe. *Sac*I digestion of normal mouse DNA yielded three endogenous c-*abl*-containing fragments with molecular weights of 16, 5.8 and 3.0 kilobase (kb)[9] (Fig. 1). As *Sac*I cleaves within the AbMuLV long terminal repeat present at both ends of integrated viral DNA and at one internal site in the v-*abl* sequences[9], DNA of AbMuLV-infected cells (for example, B6T4E4 tumour cells) yielded two additional exogenous v-*abl*-containing *Sac*I fragments of 3.2 and 3.5 kb (Fig. 1*a*). Similar exogenous v-*abl* *Sac*I fragments were detected in B6T1E2 DNA (not shown). In contrast, DNAs of three NIH cell lines transformed by B6T4E4 tumour DNA (Fig. 1*c–e*) and of three NIH cell lines transformed by B6T1E2 tumour DNA (Fig. 1*f–h*) yielded only the endogenous c-*abl*-containing *Sac*I fragments detected in DNA of untransformed NIH 3T3 cells (Fig. 1*b*). These observations were confirmed by analysis of *Bam*HI-digested DNAs. NIH cells transformed by B6T4E4 tumour DNA (Fig. 1*k–m*) contained only the endogenous c-*abl* sequences present in DNA of NIH 3T3 cells[9] (Fig. 1*j*), whereas additional exogenous v-*abl* sequences were detected in DNA of B6T4E4 tumour cells (Fig. 1*i*). The absence of exogenous v-*abl* DNA in NIH cells transformed by DNAs of AbMuLV-induced tumours indicates that the transforming activity of these tumour DNAs is not mediated by transfer of the AbMuLV genome. As none of the six transformed NIH cell lines contained exogenous AbMuLV sequences, it seems that the transforming activity of AbMuLV DNA is significantly lower than that of the transforming gene detected in these transfection assays.

The transforming genes detected by transfection of AbMuLV-induced tumour DNAs were further characterized by investigating their sensitivity to cleavage with restriction endonucleases. Transforming activities of DNAs of both tumours studied were inactivated by digestion with either *Bam*HI or *Xho*I but not by digestion with *Eco*RI or *Hin*dIII (Table 2). In contrast, transforming activity of AbMuLV DNA is not affected by digestion with *Bam*HI[10]. The susceptibility of AbMuLV-induced tumour DNAs to restriction endonuclease digestion is the same as that previously reported for DNAs of four human pre-B-lymphocytic neoplasms, but differs from the patterns of inactivation observed for transforming activities of DNAs of human and mouse neoplasms representing intermediate and mature stages of B- and T-lymphocyte differentiation[7]. These results indicate that the transforming gene detected by transfection of DNAs of AbMuLV-induced mouse pre-B-lymphocyte neoplasms is closely related to the transforming gene activated in human pre-B-lymphocyte neoplasms.

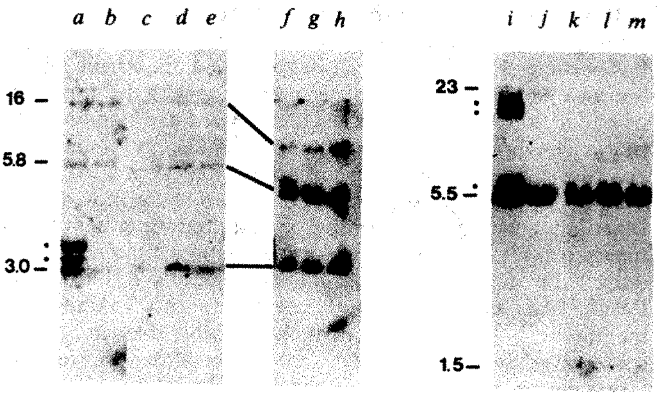

Fig. 1 Analysis of *abl* sequences in transformed NIH cells. Cellular DNAs were digested with either *Sac*I (*a–h*) or *Bam*HI (*i–m*), electrophoresed in agarose gels and analysed by Southern blot hybridization[18] as described previously[7] with ^{32}P-DNA probe prepared by nick-translation of a 1.5-kb v-*abl*-containing *Bgl*II fragment of λAM-1 (ref. 8). *a*, *i*, B6T4E4 DNA; *b*, *j*, NIH 3T3 DNA; *c–e*, *k–m*, DNAs of three independent lines of NIH cells transformed by B6T4E4 DNA; *f–h*, DNAs of three independent lines of NIH cells transformed by B6T1E2 DNA. The molecular weights of the endogenous normal mouse c-*abl* fragments[9] are indicated in kb. Dots indicate exogenous v-*abl* fragments in B6T4E4 DNA.

Table 1 Transforming activity of DNAs

Donor DNA	Total foci/total recipient cultures	Foci per μg DNA
AbMuLV-induced tumours:		
B6T4E4	321/14	1.1
B6T1E2	416/16	1.3
Transformed NIH cells:		
NIH (B6T4E4) 3-2	51/6	0.43
NIH (B6T4E4) 3-1	85/6	0.71
NIH (B6T4E4) 1-1	93/5	0.93
NIH (B6T1E2) 4-1	56/6	0.47
NIH (B6T1E2) 1-2	58/6	0.48
NIH (B6T1E2) 1-1	47/6	0.39
Controls:		
Normal mouse thymocytes	0/15	<0.003
Salmon sperm	6/100	0.003
Normal mouse liver	0/20	<0.003
NIH 3T3	0/25	<0.002

NIH 3T3 cells were exposed to 20 μg of donor DNA per recipient cell culture and foci of transformed cells were counted 11–13 days after transfection[7]. B6T4E4 and B6T1E2 are AbMuLV-induced mouse pre-B-lymphocyte neoplasm cell lines. Three independent foci of NIH cells transformed by each of these tumour DNAs (designated NIH (B6T4E4) and NIH (B6T1E2) cells) were grown to mass culture and used as donors of DNA in secondary transfection assays. Control DNAs were from normal mouse tissues, NIH 3T3 cells and salmon sperm.

Table 2 Digestion of tumour DNAs with restriction endonucleases

	Foci per μg DNA				
	Undigested	*Bam*HI	*Eco*RI	*Hin*dIII	*Xho*I
B6T4E4	1.0	0.01	1.1	1.2	0.06
B6T1E2	0.75	0.01	0.95	1.3	0.03

DNA (80 μg) of AbMuLV-induced tumours was digested to completion with the restriction endonucleases indicated. Bacteriophage λ DNA (2 μg) was included in a separate aliquot of each reaction that was incubated in parallel and analysed by electrophoresis in agarose gels to monitor the specificity and extent of digestion. Transforming activities of digested and undigested DNAs were assayed by focus formation on NIH 3T3 cells.

Previous studies have identified transforming genes in neoplasms induced by the weakly oncogenic retroviruses avian lymphoid leukosis virus (LLV), mouse mammary tumour virus (MMTV) and murine leukaemia virus (MuLV)[7,11,12]. In contrast to acute transforming retroviruses such as AbMuLV, these weakly oncogenic retroviruses do not contain specific viral transforming genes and require long latent periods (>6 months) for induction of neoplasia. The transforming genes detected by transfection of DNAs of LLV-induced chicken B-cell lymphomas and of MMTV-induced mouse mammary carcinomas were not linked to viral DNA sequences, indicating that oncogenesis by these viruses involves indirect activation of cellular transforming genes[11,12]. In addition, restriction endonuclease analysis indicated that the transforming genes activated in MMTV-induced mammary carcinomas, or in MuLV-induced lymphoid neoplasms, were also activated in chemically induced or spontaneously occurring neoplasms of the same cell types[7,12].

Induction of chicken B-cell lymphomas by LLV also involves activation of a cellular gene (c-*myc*) homologous to the transforming gene of the acute transforming virus MC-29, by adjacent integration of exogenous LLV transcriptional regulatory sequences[13]. However, the transforming gene detected by transfection of chicken B-cell lymphoma DNAs is not homologous to c-*myc*, indicating that LLV-induced B-cell lymphomas contain at least two distinct transforming genes[14]. Since induction of lymphomas by LLV seems to be a multi-step process, it has been suggested that the two distinct transforming genes may act at different stages of neoplastic development[14].

The present experiments suggest that oncogenesis by an acute transforming virus, AbMuLV, can also involve indirect activation of a cellular transforming gene. As only two tumours were analysed in these experiments, further studies will be required to assess the generality of the results. Together with the recent findings of Whitlock and Witte[3] and Grunwald *et al.*[4], however, our results suggest the possibility that the v-*abl* gene product acts at an early stage of oncogenesis and that progression to neoplasia involves activation of a distinct transforming gene detected by transfection. Rather than inducing transformation as a single-step event, the role of v-*abl* in the neoplastic process may be similar to that of the activated c-*myc* gene in LLV-induced chicken lymphomas.

Restriction endonuclease analysis of the transforming gene detected by transfection of DNA of AbMuLV-induced pre-B-lymphocyte neoplasms indicates that this gene is closely related to one previously detected in human neoplasms of the same cell type[7]. AbMuLV has also been reported to induce neoplasms of more mature B lymphocytes[15], T lymphocytes[16] and myeloid cells[17]. It will be of interest to characterize cellular transforming genes activated in AbMuLV-induced tumours of these other cell types in relation to the stage-specific transforming genes reported in other mouse and human B- and T-lymphocyte neoplasms[7].

We thank D. Baltimore for originally suggesting these experiments, R. Risser for tumour cell lines and S. Aaronson for the λAM-1 clone. These studies were supported by NCI grants CA33108 (M.L.), CA28946 (G.M.C.), and 5S07-RR05526 (M.L.), by American Cancer Society grant IN118B (M.L.) and by an American Cancer Society Faculty Research award (G.M.C.).

Cooperative deoxygenation of haemoglobin: asymmetry of binding and subunit differences

Leonard Peller

Cardiovascular Research Institute, University of California at
San Francisco, San Francisco, California 94143, USA

Oxygen uptake by the blood in the lungs of a resting human brings the level of saturation of haemoglobin from ~70% to >97% (refs 1, 2). The recourse to this upper portion of the oxygen binding curve is reflected in an asymmetry of the isotherm which is frequently reported[3,4], but which has not been accorded any physiological role. This asymmetry is responsible for a more pronounced cooperativity of the deoxygenation at nearly complete saturation than that displayed in the typical sigmoidal pattern of loading at low oxygen tensions. Such behaviour is viewed here as a consequence of and a possible rationalization for the presence of two similar but distinct types of subunit in the haemoglobin tetramer.

A binding process would be defined as symmetrical if the fractional extent of saturation, θ minus 1/2, plotted against $\log(P/P_{1/2})$, where P is the oxygen tension and $P_{1/2}$ that corresponding to $\theta = 1/2$, yielded a curve with inversion symmetry about the origin. For ligation to a tetramer this symmetry condition would require[5] that $\sigma = (K_{2d}K_{3d})/(K_{1d})(K_{4d}) = 1$ where K_{1d}–K_{4d} are the intrinsic dissociation constants for the first to the fourth attached oxygen, respectively.

The first and last dissociation constants (K_{1d} and K_{4d}) are obtainable by extrapolation[3] as indicated in Fig. 1*a*,*b*. Greater uncertainty applies to the determination of K_{2d} and K_{3d} but their more reliably determined product[6] is sufficient, with K_{1d} and K_{4d}, to specify σ (designated W previously)[3,4]. Deviation of this parameter from unity has been adduced as evidence against several models which seek to express the four dissociation constants in terms of a smaller number of parameters[5,7,8].

From extant data for human haemoglobin stripped of diphosphoglycerate (DPG), a value of $\sigma = 29$ can be calculated[9], while $\sigma = 47$ for the same haemoglobin in the presence of DPG[10]. In contrast, a value of 84 has been reported for whole human blood[4]. Thus there is considerable variability in this parameter, due to the uncertainties in K_{2d} and K_{3d}, and because of differences in solution conditions and in measurement techniques. No values of $\sigma < 1$ have been reported and the phosphorylated co-factors[11,12], when present, elevate this parameter.

The relationship of σ to the pattern of oxygen ligation can be seen by comparing the rates of change of the slopes in Fig. 1. For the sigmoidal region at low oxygen tensions in Fig. 1*a*

$$[d^2\theta/d(P/K_{1d})^2]_{P\to 0}=2[3(K_{1d}/K_{2d})-4] \qquad (1)$$

while the comparable quantity for the dissociation curve in Fig. 1*b* is given by

$$[d^2(1-\theta)/d(K_{4d}/P)^2]_{P\to\infty}=2[3(K_{3d}/K_{4d})-4] \qquad (2)$$

The introduction of the factors K_{1d}^2 and K_{4d}^2 renders these derivatives independent of the choice of the standard state for the ligand. For a hyperbolic binding curve, as found with myoglobin or with independent binding and four identical intrinsic constants, both derivatives equal −2.

The ratio of the second derivative in equation (2) to that in equation (1) is greater than or equal to σ. It is equal only if $\sigma = 1$, in which case, changes of abscissae in the two graphs to P/K_{1d} and K_{4d}/P would make the curves superposable—another consequence of symmetry. With the cited values of σ, the sigmoidality of the dissociation curve in Fig. 1*b* as characterized by the second derivative can be 30–100 times greater than that shown in the customary binding curve of Fig. 1*a*. The asymptotic flattening in the latter provides no visual hint of the marked cooperativity of deoxygenation. Haemoglobin loads oxygen at a *p*H higher than it yields it up (Bohr effect), as indicated in Fig. 1*a*. The ratio of the sigmoidality parameters might be anticipated to be even greater at *p*H values lower than the slightly alkaline ones for which the σs quoted here apply.

A search for the origin of this asymmetry focuses naturally on the pairs of α- and β-subunits comprising the haemoglobin tetramer. A model can be advanced along the lines of those proposed previously[7] which allows for variations in reaction with oxygen of these two types of polypeptide chain in the tetramer. Such a model must minimally contain two intrinsic dissociation constants $K_{\alpha d}$ and $K_{\beta d}$ for the desorption of the first oxygen bound, respectively, to one α- and one β-subunit. Four interaction parameters, $\rho_{\alpha\alpha}$ and so on (see Fig. 2), measure the extent of diminution of dissociation from one haem site effected by oxygens occupying neighbouring sites. These quantities are expected to have an upper limit of unity with strong repression of dissociation characterized by magnitudes substantially less than one. They can be related directly to the conditional free energies of site occupancy[13]. Expressions for the four intrinsic dissociation constants involve all six of the above parameters. The asymmetry is given by

$$\sigma=[(K_{\alpha d}+K_{\beta d})^2\rho_{\alpha\alpha}\rho_{\beta\beta}]/[(K_{\alpha d}\rho_{\alpha\alpha})+(K_{\beta d}\rho_{\beta\beta})]^2 \qquad (3)$$

The cross-interaction parameters $\rho_{\alpha\beta}$ and $\rho'_{\alpha\beta}$, of which two were introduced because each subunit is differently disposed structurally in the tetramer with respect to its two dissimilar neighbours[14], are absent from equation (3). This is because their magnitudes, which affect equally both α and β, cannot contribute to the asymmetry. From equation (3) $\sigma = 1$ if $\rho_{\alpha\alpha} = \rho_{\beta\beta}$ or $K_{\alpha d}\rho_{\alpha\alpha}^2 = K_{\beta d}\rho_{\beta\beta}^2$.

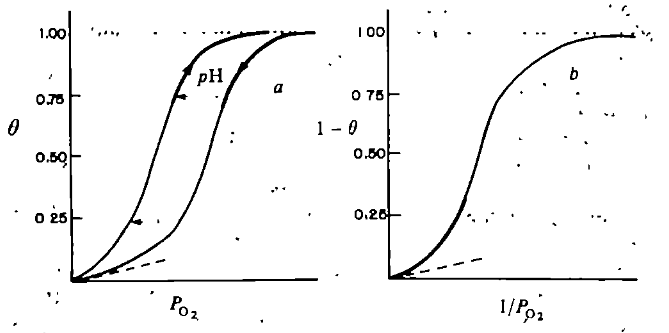

Fig. 1 *a*, Customary curves for oxygen loading (left) and unloading (right) by haemoglobin. The darker portions of the curves indicate the operative region in resting humans. The broken line is the initial tangent given by $[d\theta/dP]_{P\to 0}=1/K_{1d}$. *b*, Fractional extent of unsaturation plotted against $1/P$ to illustrate the highly cooperative deoxygenation reaction. The limiting tangent at high oxygen tension as shown by the dashed line is $[d(1-\theta)/d(1/P)]_{P\to\infty}=K_{4d}$.

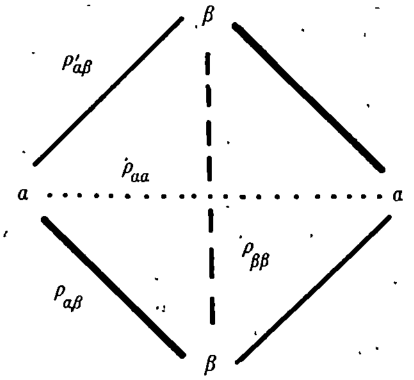

Fig. 2 The haemoglobin tetramer with six edges marked by parameters for repression of dissociation induced by intersubunit contacts. They are formally represented as two site–site interactions between like neighbours ($\alpha\alpha$ and $\beta\beta$) and two ($\alpha\beta$ and $\alpha\beta'$) pairs of interactions between unlike partners.

The condition of practical interest of $\sigma > 1$ can be shown to mandate either of two pairs of inequalities, that is, $\rho_{\alpha\alpha}/\rho_{\beta\beta} > \sigma \simeq$ 30–90 and $K_{\beta d}/K_{\alpha d} > \sigma^{1/2} \simeq 5$–9, or the opposite obtained by interchanging α and β. Site–site as opposed to single site interaction accounts for the higher power of σ appearing in the first inequality. This is the experimentally favoured pair as it requires that the β-chains, which self-aggregate and are in more intimate contact[14] in haemoglobin A, are the more efficacious in depressing the dissociation constants. Also, the companion inequality is consistent with reports[15–17] that the α-chains are the first to bind oxygen.

While intense physical activity can cause blood in the pulmonary capillary bed to be more deprived of oxygen[1] than the 70% level cited above, the usual oxygen tension must convert it overwhelmingly (and rather rapidly[18]) to quite high extents of saturation. Thus the cooperative character to the oxygenation must be of secondary importance to that exhibited by the deoxygenation in states of physiological stress. The asymmetry of the ligation clearly serves this purpose. An asymmetry of reaction assignable to a structural cause is comprehensible. However, the existence of two kinds of subunit in haemoglobin is of wide occurrence, even among primitive vertebrates. Is its origin as well as its preservation attributable to the need for these diverse organisms to maintain a capacity for an asymmetric response to oxygen requirements?

Many of the conclusions about the quantitative behaviour of haemoglobin have been reached independently by Dr Gregorio Weber through consideration of the general consequences of asymmetric ligation. I thank Drs John Severinghaus and Peter Torgerson for helpful comments and the NSF for support (grant PCM-8022006).

BOOK REVIEWS

A philosopher among the physicists

Donald MacKay

Postscript to the Logic of Scientific Discovery, Vols II and III. By Karl Popper, edited by W.W. Bartley, III. Vol. II *The Open Universe: An Argument for Indeterminism.* Pp.185. ISBN 0-09-146180-4. Vol. III *Quantum Theory and the Schism in Physics.* Pp. 229. ISBN 0-09-146170-7. (Hutchinson/Rowman & Littlefield: 1982.) Each volume £15, $24.50. Vol. I, *Realism and the Aim of Science,* has just been published in the United States and will appear in Britain early next year.

Sir Karl Popper is not the kind of original thinker who is content to swim peacefully against the stream of contemporary fashion. Instead, he takes Puckish delight in splashing the water in the faces of those who drift unthinkingly by. "Many younger physicists", he laments, "have grown up in a period of over-specialisation, and in the newly developing tradition of the cult of narrowness, and the contempt for the non-specialist older generation . . . a tradition which may easily lead to the end of science and its replacement by technology". He sees the current scientific orthodoxy as riddled with philosophical errors and confusions that urgently need sorting out; but where a lesser mind might be moved to attack these with grim and tedious analyses in abstract terms, it is Popper's genius to make the issues come alive in terms of actual events and concrete problems in the history of science, as seen by the people who faced them. The result is extraordinarily stimulating, whether or not one agrees with him. To come to grips with his thinking is to have one's mental muscles enjoyably stretched, and one's presuppositions submitted to searching scrutiny in an almost playfully challenging — though deadly serious — spirit.

These two volumes are part of a trilogy based on Popper's legendary *Postscript to The Logic of Scientific Discovery,* which after circulating privately for 25 years has now acquired a variety of qualifying and amplifying addenda. In Vol. II, *The Open Universe,* Popper is concerned mainly with refuting the idea that the world is deterministic in any of several senses which he explores. Three addenda argue for the reality of worlds other than the physical; and against ontological reductionism. Volume III, *Quantum Theory and the Schism in Physics,* is a hard-hitting attack on the subjectivist interpretation of quantum mechanics favoured by the Copenhagen School, and on what Popper sees as kindred interpretations of the Second Law of Thermodynamics. It includes a detailed argument for his well-known explication* of probability as "objective propensity", and ends with a "Metaphysical Epilogue" on the nature of science and its open problems, as seen in terms of his objectivist propensity interpretation.

What invigorates in Poppor is his robust and commonsensical realism. "Realism", he declares, "is linked with rationalism, with the reality of the human mind, of human creativity, and of human suffering". He scorns claims such as Wigner's that the laws of quantum mechanics cannot be formulated without recourse to the concept of consciousness, as

> based on bad philosophy and on a few very simple mistakes [which] I hope will soon be forgotten, while the great physicists who happened to commit them will be forever remembered by their marvellous contributions to physics: contributions of a significance and depth to which no philosopher can aspire.

He rebuts the idea that von Neumann conclusively proved the impossibility of "hidden variables"; and he effectively demolishes much subjectivist nonsense talked about the famous "Reduction of the wave packet". No teacher of quantum theory should miss the opportunity to sharpen his thinking against this abrasive whetstone, especially if he wants his pupils to distinguish solid science from fashionable dogma.

In his Epilogue Popper strikes an optimistic note, suggesting that by replacing talk of "particles" by talk of "propensities" as the objectively real elements of the physical theory of matter, the wave–particle dualism of orthodox theory could be dispensed with, and the dispute between Einstein's and Born's interpretations resolved. Particles, he tells us, "can be produced by propensities, and . . . up to a point . . . *are* propensities" (Vol. III, p. 196). One might have expected propensities to be linked more closely with events than with entities — with particle-impact and the like, rather than with particles; but Popper evidently has in mind Dirac's theory of the positron as an analogous line of thought (Vol. III, p.197). The Epilogue unfortunately does not go into enough detail to allow the fruitfulness of his suggestion to be assessed.

In his hot pursuit of subjectivity, there are times when Popper's polemical zeal drives him to cut some corners. Against subjectivist notions of entropy, for example, he offers as an objective criterion of disorder in a system the "chancelikeness" of the distribution of its molecules (Vol. III, p.112). Obvious counter-examples spring to mind: If a (highly-ordered) busload of soldiers scatter to precisely specified but randomly distributed hiding places, are they now any less orderly? Is the sequence of digits down the columns of a telephone directory "disorderly"? Compactness is only one form of order; and dispersion is not the same concept as disorder. Everything here depends on the data that determine the distribution of the dispersed members. To claim that Boltzmann's entropy-measure is *relative* to a specific data-base does not make it subjective; and the link between disorder and lack of information cannot be dismissed quite as easily as Popper suggests.

A passionate concern for human freedom and dignity shines through Popper's polemics against determinism, which he sees as incompatible with responsible choice and human creativity. He argues convincingly that deterministic concepts of our world have no scientific support; and he sets out in improved form his famous 1950 proof that no discrete-state computing machine could predict precisely the future of a universe that included itself, even in terms of the laws of classical (pre-Heisenberg) physics.

Even if we accept all this, however, and thoroughly sympathize with its motivation, some nagging doubts remain. First, as Popper himself acknowledges, our inability to predict a future event is neither a necessary nor a sufficient condition of its being undetermined; so his heavy emphasis on the unpredictability-to-us of the future can here be misleading and even counterproductive. Secondly, indeterminism would be of value in this connection only if it allowed scope for the control of human actions by human conscious choices; but for this Popper can only ask us to picture the mind (in a non-physical "World 2") as "interacting" with the brain (in "World 1"), without offering any scientific account of how such interaction could take place, let alone how his conjecture could be falsified. (His more extensive treatment of the topic with Sir John Eccles in *The Self and its Brain* (Springer-Verlag, 1977) still leaves these matters unclear.)

---

*For Popper the "probability" of a physical event denotes an objective physical property of the generating situation, which he terms its "propensity" to produce the event.

My main doubt, however, is whether Popper has shown human freedom and creativity to *require* the brain to be physically indeterminate in its workings. He rejects — for good reasons — the simple equation of mind with brain; but he ignores another option which, as I see it, would safeguard all the values he wants to maintain without the awkward implications of interactionism. This would see mental activity, rather than *interacting with* the brain, as *embodied in* brain activity, in something of the sense in which an equation being solved by a computer is embodied in the computer's physical structure at the time. To say that the behaviour of a computer is determined by the equation it is solving, is quite compatible with saying that its physical workings are determined by the laws of physics. Indeed, from the programmer's standpoint, the latter may be a necessary condition of his claim; and there is certainly no need to prove the computer open to "non-physical influences from another world" in order to sustain that claim.

Courtesy Hutchinson

Karl Popper — "extraordinarily stimulating, whether or not one agrees with him".

Scientific determinism (in Popper's sense) may well be false and baseless; but for his elaborate attack on it to be of much consequence for human freedom he needs to show why the physical determinateness of brain processes would preclude the capacity of human beings to determine their actions freely in accordance with their conscious thinking, evaluating and choosing. As I have argued elsewhere — see *Mind* **69**, 31-40 (1960), and *Human Science and Human Dignity* (Hodder and Stoughton, 1979) — even if the outcome of such choosing were predictable by non-participant observers, it would not logically follow that the outcome was inevitable for the chooser himself, nor that *he* had really no options open to him; for this, too, is an objectively relativistic situation. What the non-participants would be correct to believe about the immediate future of the chooser's cognitive mechanism is something the chooser himself would in general be mistaken to accept as accurate and inevitable-for-him, since the physical changes required for its embodiment in his brain cannot but significantly affect its accuracy. Thus even the complete success of a prediction kept secret from the chooser until after the event would not show in retrospect that *he* had no other option open to him; for no prediction of the outcome existed, even unknown to him, that had an unconditional claim to *his* assent. There is, after all, nothing particularly shocking in the thought that the form of a future event may be fixed-and-inevitable relative to someone not causally coupled to it, while still indeterminate and open to the individual whose thinking and deciding will constitute the event in question.

This relativistic point bears particularly on Popper's dispute with Einstein over the implications of the latter's deterministic world-model, as narrated in Vol. II, pp.89-92. According to Popper, Einstein's views in 1950 implied that the future is contained in the past "as the chick in its egg". This, Popper argued, made the future "superfluous", and our sense of time "illusory". Moreover, "if we were experiencing successive [motion picture] shots of an unchanging world, then one thing at least was genuinely changing . . . our conscious experience" (Vol. II, p.92), and this "looked very much like a flat contradiction". As soon as we distinguish the different standpoints here, however, all appearance of contradiction vanishes. From the standpoint of the characters in a film (or a history book) their future is asymmetrical with their past in that, willy nilly, what they think and desire and do will play a part in determining its form. Their experience of change is not an illusion, but a fact of their world that they would be lying to deny. From the standpoint of the film-projectionist (or the book-reader), of course, the future of the characters is as much a fixed and unchanging fact-for-him as their past. It is "all in the book". To regard these views as logically conflicting, however, is surely a mistake; for the data available to the projectionist (or the bookreader), so far from showing the experience of the characters to be "illusory", actually supply confirmatory evidence of the changes experienced in their world, and of the asymmetry-to-them of past and future. It is thus rather touching to be told that the ageing Einstein, when confronted with Popper's arguments, merely "said that he was impressed by them, and that he had no answer for them" (p.92).

A reviewer's task is to be critical where he must; and indeed only lack of space precludes comment on a number of other matters, such as Popper's interpretation of the quantum-mechanical ψ-function, his tendency to confound rationality and rationalism, and his inclination to take "World 1" (the world of physical objects) as the "standard example of reality". Let me conclude, however, by warmly recommending the catalytic experience of reading — and re-reading — these mature and scholarly reflections of a great mind, on matters of central concern to physical science and of importance to us all. ☐

Digging deep into plasma physics

T.J.M. Boyd

The Interaction of Strong Electromagnetic Fields with Plasmas. By I.R. Gekker. Pp.324. ISBN 0-19-851467-0. (Oxford University Press: 1982.) £35, $85.

The coming of age of plasma physics has been reflected in its literature by a steady growth in the output of monographs as compared with the primers of years past. There has appeared lately a stream of more or less specialized works addressing topical — occasionally, by the time the books appear, not-so-topical — aspects of what is now a wide-ranging subject. Professor Gekker's book on the interaction of strong electromagnetic radiation with plasmas is avowedly specialist, and its content undeniably topical.

The text is in two parts. Part I summarizes the simple linear physics of plasma wave propagation, with a short excursion into electromagnetic wave absorption in inhomogeneous plasmas which serves as an introduction to the theme of the work proper. Part II consists of six chapters devoted to aspects of the nonlinear physics of propagation and absorption of electromagnetic waves, a subject to which Professor Gekker has himself contributed widely. Starting with a statement of the properties of nonlinear phenomena in plasmas — at four pages a *précis* of almost unbecoming brevity — Part II goes on to develop the interaction physics of charged particles with high frequency fields in both magnetized and unmagnetized plasmas. This is followed by a chapter on the interaction of strong electromagnetic fields with dense plasmas, altogether too ambitious a title in view of its very restricted compass. The final two chapters on the anomalous absorption of electromagnetic radiation and concomitant plasma heating are, by contrast, full and detailed and make up almost half the text. The book concludes with an extensive bibliography and a less than comprehensive index.

The work is given a distinctive flavour by its emphasis not only on the experimental aspects of the interaction of radiation with plasmas but on details of the experimental procedures themselves. While there are undeniably circumstances in which this amount of detail is valuable — even essential — one is left with a clear impression that on many occasions the descriptions provided serve no purpose and could have been dispensed with to advantage. Worse, however, is that they sometimes positively get in the way of an otherwise informative discussion. Examples of such over-indulgence are to be found in virtually every section of Part II. Some read like paraphrases of the original literature; others are probably relics from the lectures on which the book is based and would have been best left out. Had Professor Gekker been less prodigal in his attention to descriptive detail he might have felt able to devote correspondingly more space to discussing the implications of the various experiments for nonlinear plasma physics.

Another shortcoming, perhaps not unrelated to the book's origins in a course of lectures, is some tendency to be comprehensive rather than critical. While it is informative to have one experiment compared and contrasted with another, there is perhaps less merit in setting out a catalogue of work done without critical commentary. Another aspect of the same problem manifests itself in the lists of authors which are interspersed in the text, extending in one instance to 12 lines of unnecessary interruption. More substantial than these pinpricks is the considerable imbalance in the treatment of the subject matter. For example Chapter 9 forms almost one-third of the text, with one section alone (Section 9.5 on microwave absorption experiments) extending to 35 pages. This could have been subdivided to advantage.

These various criticisms should not be taken to imply that the book is without merit. It is a veritable mine of information — albeit one in which much of the ore is deep level — and will repay careful reading. The readership is likely to consist in large part of scientists active in this area of plasma physics. Unlike the original Russian version this translation is less likely to be used as a text in postgraduate courses though it could, and should, find a place on reading lists. ☐

T.J.M. Boyd is Professor of Applied Mathematics in the University of Wales at University College, Bangor.

Abscission since Newton

Roy Sexton

Abscission. By Fredrick T. Addicott with illustrations by Alice B. Addicott. Pp.369. ISBN 0-520-04288-3. (University of California Press: 1982.) £29.75, $51.35.

LIKE MOST abscission physiologists I am occasionally confronted by some hearty soul who tells me that we would probably know more about abscission if only Newton had confined his thoughts to the processes that occurred just prior to the fall of the apple. The implication that there are major gaps in our knowledge of abscission is well founded but unfortunately these problems have failed to attract the attention they merit from botanists.

In the preface to *Abscission*, F.T. Addicott makes plain his aim to interest plant scientists from a wide range of backgrounds. Unlike most previous reviewers, he has not confined his attention to the physiology and agronomic importance of the process but has expanded the scope to include the lower plants and topics such as the genetics and ecology of abscission. During his 40-year association with the subject the author has accumulated 2,500 papers concerned with abscission and as a result he is able to write with unrivalled authority on most aspects of the process. The obvious zeal with which this information has been gathered is impressive, though great care has been taken not to overwhelm the reader and the information is presented in a concise yet readable form. There is little doubt that the massive effort involved in mastering this material has been worthwhile and will ensure that this volume will become the standard reference work for many years to come.

The first section of the book describes the various structures that can be shed from the plant, ranging in size from the smallest trichomes to the complete aerial portion of tumble weeds. Detailed accounts are given of the anatomy, cell biology and biochemistry of the weakening process. The section on the hormonal control of abscission is briefer than I had anticipated, and although the literature coverage is adequate it is not as comprehensive as that in other chapters. This section contains a spirited defence of the view that abscisic acid is a major controlling factor in abscission, which is perhaps what one would expect from a member of the team involved in the original characterization of the substance.

Also included are a chapter describing the increasing agronomic importance of manipulating abscission and another concerned with the ecological significance of different abscission strategies. The sections on the genetics and evolution of abscission are especially noteworthy because they represent the first serious attempts to review these subjects.

The front cover of the book carries not only the author's name but also that of his wife, Alice B. Addicott, who was responsible for the fine botanical drawings. This pleasant feature draws attention to the unrecognized yet important role that illustrators play in improving the clarity of scientific texts. However I appreciate mention of her name for another reason. I was once asked by a student why the recognized abbreviation for abscisic acid was ABA (see *Science* **159**, 1493; 1968) and not AbA which seemed more logical. Is this perhaps just a coincidence; or is there another explanation? ☐

Roy Sexton is a Lecturer in the Department of Biological Science at the University of Stirling.

Variety in singular behaviour

N.B. Davies

The Shelduck: A Study in Behavioural Ecology. By I.J. Patterson. Pp.276. ISBN 0-521-24646-6. (Cambridge University Press: 1982.) £27.50.

THE CURRENT trend for research in behavioural ecology is first to think of an interesting idea and then of a species that will be good for testing it. Detailed studies of all the various aspects of a single species have become less fashionable and are sometimes disparagingly labelled "the aardvark approach"; if no one has yet studied aardvarks then we use this as the main excuse for doing research on them. This view is unfortunate because we have only to think of Lack's robins, Nice's sparrows and Tinbergen's gulls to remind us that some of the main ideas in behaviour and ecology have been derived from long-term studies of particular species.

Shelducks have been studied on the River Ythan in Scotland for the past 20 years by Ian Patterson and students from Aberdeen University, forming the subject of six theses and over 20 published papers. This book, which summarizes the work and relates it to other studies, is a good example both of how general theories can best be tested with long-term data and also of how a detailed study of one species can give rise to new ideas of wider interest. The book is organized around the shelduck's annual cycle, beginning with the extraordinary autumn migration to the mudflats of north-west Europe where, safe from predators, thousands of birds congregate to moult, dropping all their flight feathers

simultaneously and so becoming flightless for about a month. Then there follow chapters on winter flocking, territories, nest sites, laying and incubation, care of the young and population regulation.

The first workers in the 1960s interpreted much of the shelduck's social behaviour and population dynamics in relation to Wynne-Edwards's theory of reproductive restraint by individuals in order to prevent over-population. The groups of birds which assembled in the sand dunes in spring were regarded as "parliaments", where decisions were made for the good of the group as to who should breed and who should be excluded. Patterson's studies have shown that this behaviour makes much better sense from a selfish-individual point of view. The non-breeders turn out to be mainly young birds prospecting for nest burrows late in the season, probably to gain familiarity with the breeding area for the next year. The parliaments appear to involve subordinate or previously unsuccessful birds following dominants around to parasitize their knowledge of nest sites. There is also the possibility that "non-breeders" in fact dump eggs in the breeders' nests; up to half of the nests in some years contain eggs laid by more than one female. Shelducks are so shy, however, and their nests at the ends of rabbit burrows are so inaccessible, that the details of these multiple clutches are still unknown.

Equally fascinating is the phenomenon of brood mixing. When parents escort their ducklings from their burrows in the dunes to feeding grounds on the estuary, they often encounter other families. During the aggressive encounters between adults, ducklings often attach themselves to the wrong parents. Some pairs may lose all their young while others accumulate large crèches. The data on duckling survival show no benefit to the young from these associations and measurements of adult survival suggest likewise no benefit to either donor or recipient parents. Patterson suggests therefore that brood mixing is not adaptive and occurs when shelducks breed at unusually high densities. Fervent adaptationists will probably want more data before they are convinced, but critics of the so-called adaptationist programme will perhaps be relieved to find that animals sometimes simply make mistakes!

One of the main messages which comes out of this excellent book, and from other long-term studies like it, is that there are not only marked differences between populations but also between years within the same population. Such variability makes field work all the more interesting, but it means that we need to be careful before we generalize from the findings of short-term research projects. ☐

N.B. Davies is Demonstrator in Zoology at the University of Cambridge and a Fellow of Pembroke College.

The planets exposed

Dennis L. Hartmann

The Cambridge Photographic Atlas of the Planets. By Geoffrey Briggs and Frederick W. Taylor. Pp.255. ISBN 0-521-23976-1. (Cambridge Unversity Press: 1982.) £12.50, $24.95.

We are nearing the end of a remarkable period of exploration of the Solar System. Six of the nine planets and their satellites have been the objects of close scrutiny by unmanned probes; pictures and data have been returned to Earth from the surfaces of our nearest planetary neighbours; men have walked on the Moon. All of this has taken place in the past 20 years, most of it in the past decade.

The early symbol of a new public awareness of the Solar System and our place in it was perhaps the sight of Earth from the vicinity of the Moon obtained by the Apollo astronauts. In *The Cambridge Photographic Atlas of the Planets* this perspective on our familiar planet and its satellite is supplemented by a large number of close-up photographs and other images of five additional planets and most of their satellites. It is this new view of the Solar System, obtained mostly from unmanned spacecraft, which Briggs and Taylor present in their book.

The authors begin with an overview of current ideas regarding the origin and subsequent evolution of the Solar System, directing particular attention towards the formation of the planets and the processes acting to determine the properties of their surfaces and atmospheres. This account provides the background for the six main chapters in which the planets are discussed in order of increasing distance from the Sun, beginning with the rather Moon-like planet Mercury and concluding with the intricate and still somewhat mysterious Saturnian System.

Each chapter opens with a section of text, first describing the overall characteristics of the planet and then delving into the scientific questions they present. Observations obtained by remote probes have provided many clues about the history and current state of the interiors, surfaces and atmospheres of the planets and their satellites, and these new findings are outlined both readably and authoritatively. Following the text comes a section of photographs and maps showing the surface or atmosphere of the planet in question and those of its satellites. The pictures, about half of them reproduced in colour, include some of the most spectacular and beautiful available, but many have also been chosen because they illustrate some interesting feature or provide some important clue about the body in question. A careful reading of the text heightens one's interest in the pictures, but lucid yet detailed captions mean that it is not necessary to read the text to appreciate the significance of the illustrations.

The fascinating observations of the planets and their satellites illustrated and discussed in this book are likely to provoke the interest even of those with no previous exposure to planetary science. One can ponder such questions as whether there are continents on Venus and how the peculiar patterns in the clouds of its atmosphere are maintained. The surface features of Mars, the circulation of the atmosphere of Jupiter and the rings of Saturn provide equally challenging opportunities for inquiry and debate. Some readers, however, will be disappointed that no bibliography or source list is included to enable them to probe such issues more deeply.

Geoffrey Briggs and Frederick Taylor have a long-standing involvement in planetary exploration and write clearly and engagingly about their subject. Their book is likely to please a wide range of readers. The text should be comprehensible to the general reader, though it will be better understood and appreciated by those with some knowledge of the physical sciences. Because of its remarkable combination of strong visual appeal and scientific interest, *The Cambridge Photographic Atlas of the Planets* will be equally at home on the coffee table and in the research library.

Dennis L. Hartmann is an Assistant Professor of Atmospheric Sciences at the University of Washington, Seattle.

Wooden characters brought to book

Peter D. Moore

Identification of Modern and Tertiary Woods. By A.C. Barefoot and Frank W. Hankins. Pp.220. ISBN 0-19-854378-6. (Oxford University Press: 1982.) £47.50, $98.

FROM the title of this book, one might be forgiven for thinking that the volume will provide a means for the identification of woods, both Tertiary and modern; in fact it does not. It sets out to illustrate those features of wood anatomy which can most usefully be applied to the characterization and identification of timber. It is, therefore, a guide for both students and timber technologists which will enable them to use with greater confidence some of the multiple-entry card keys currently on the market. Much of the book is actually based upon one of these keys, available on microfiche from Harvard University, which is itself a compilation of earlier keys and is still incomplete at present.

The opening chapter asks the question, "Why identify and study wood?", but fails adequately to answer it. It is in any case a rather superfluous question since the reader presumably has his own reasons, but a survey of these reasons could be of general interest.

There follows an introductory chapter on wood anatomy, preceding the more detailed analysis of key features used in wood identification. This account lacks structure in the way it deals with topics and fails adequately to define certain terms. Even such a straightforward expressions as "bark" are not clearly defined in the text and the drawings are sometimes so dense that the lines from labels are lost in them. More subtle terms, such as "roey-grained", are used but not explained. One redeeming feature is the use of some excellent scanning electron micrographs, a technique which could have been further exploited and improved by detailed labelling — one photograph has letters attached but lacks an explanation in the legend. As an introduction to wood anatomy, one wonders whether this chapter is indeed aimed at the newcomer or, more likely, the experienced botanist.

The main body of the book explains each of the 86 wood characters used in the punch card key, sometimes a difficult task, especially when such characters as "late wood conspicuous" need to be interpreted. On the whole, this section of the book is very helpful, especially in its profuse use of high-quality micrographs and detailed line drawings; indeed, it is hard to imagine how the key could be tackled without its aid. Finally, the arrangement of the card key is explained and a timely caveat is given concerning the variability of wood within species as a consequence of both geographical range differences and variation in environmental factors.

Taken as an illustrated adjunct to the punch card key, this volume is an extremely valuable asset. It should not, however, be regarded as a textbook of wood anatomy or as an identification manual in its own right. □

The noise of music

H.C. Longuet-Higgins

Music, Mind, and Brain: The Neuropsychology of Music. Edited by Manfred Clynes. Pp.430. ISBN 0-306-40908-9. (Plenum: 1982.) $39.50, £24.89.

THE literature of music psychology — and *Music, Mind, and Brain* is no exception — deals with a wide variety of topics ranging from the neurophysiology of pitch perception to the affective responses of listeners. In order to bring some semblance of order to this vast area of inquiry it would therefore seem essential for anyone writing about the psychology of music to distinguish clearly at the outset between auditory stimuli in general and music in particular. The most interesting questions in the subject surely have to do with the differences between our responses to different pieces of music, but without a clear definition of what counts as a piece of music it is impossible to formulate such questions precisely. If music were simply — as Charles Lamb once complained — "the noise that they make on purpose", then folk tunes, electronic squawks, animal noises and so on would have to be treated on an equal footing by the psychologist of music.

It seems to me that what distinguishes music from non-music is how we conceptualize it: a piece of music is a composition of notes, linked together by rhythmic and tonal relations, just as a sentence is a linguistic structure composed of words which are connected by syntactic and semantic relations. Modern theoretical linguistics became a science when this perspective finally came into focus, and thanks to the work of Chomsky and his successors it is now possible to see that the central problems of language have to do with the systematic relations between the detailed structures of utterances and the messages which they serve to convey. No psycholinguist would now dare to publish a paper which treated utterances or texts as unstructured sequences of noises or marks, and one might have hoped that an equivalent distinction would be taken for granted by psychologists of music. But with one or two laudable exceptions, the authors of *Music, Mind, and Brain* seem quite unaware of the need to explain, when they use the word "music", exactly what they are talking about.

The book contains 21 chapters, together with a preface, a foreword and some appendices; a short sound sheet is tucked into the back of the book. The great majority of the contributions consist entirely of words, with no musical quotations; of the remainder only a handful make any attempt to describe in detail the rhythmic or tonal structures of the musical examples. In the first three chapters, for instance, Minsky, Pribram and Roederer discourse upon musical cognition, the mechanisms of auditory memory and other broad questions, but are lamentably vague about music itself. In two other chapters Clynes and his colleagues discuss the "essentic forms" of seven basic emotions, and the characteristic "pulse" by which a composer, they claim, hall-marks his compositions; but they fail to offer any empirical tests by which this claim could in principle be falsified.

Chapter 5, by Jackendoff and Lerdahl, is possibly the best in the book. These authors clearly recognize the central importance of structural concepts in the description of music, but even they omit to give any precise account of tonal relations, or to explain, for instance, the relation between the time signature of a classical composition and rhythmic structures of the individual bars. Of the remaining contributions, the most interesting are those of Diana Deutsch on the concept of Gestalt in music, of Sundberg on the expression of emotion in singing, and of Makeig on the theory of tonality. Makeig is familiar with the current theory of tonal relations but seems to be unaware of the insights expressed by the late Deryck Cooke in his classic book *The Language of Music* (Oxford University Press, 1959).

Elsewhere, Balzano offers a group-theoretical account of "pitch sets", and rediscovers the three-dimensional tonal space first proposed by Longuet-Higgins in 1962, but does not illustrate his proposals with any interesting musical examples. And Terhardt, an acknowledged authority on auditory pitch perception, proposes a musically outrageous "root sequence" for the first few bars of *Tristan und Isolde*, in which the augmented 4th (F to B) in the famous chord is implicitly misrepresented as a diminished 5th (E sharp to B). In all it seems that some neuropsychologists of music have much to learn before their ideas need to be taken very seriously by competent musicians. ☐

Christopher Longuet-Higgins is Royal Society Research Professor in the Centre for Research on Perception and Cognition, University of Sussex.

Pascal's mind and Pascal's science

A.W.F. Edwards

Pascal: Adversary and Advocate. By Robert J. Nelson. Pp.286. ISBN 0-674-65615-6. (Harvard University Press: 1982.) $22.50, £18.

BLAISE Pascal was born in 1623 in Clermont, France. In 1631 his father Etienne Pascal (himself an able mathematician who gave his name to the "limaçon of Pascal") moved to Paris in order to secure his son a better education. There, Etienne was one of the founders of Marin Mersenne's "Academy", the finest exchange of mathematical information in Europe at the time. To this informal academy he introduced his son at the age of 14, and Blaise immediately put his new source of knowledge to good use, producing (at the age of 16) his *Essay pour les Coniques* based on the work of Desargues, another founder-member of the Academy.

In the succeeding years the young Pascal designed and had built the first mechanical adding machine and conducted experiments into the nature of a vacuum, but his chief scientific contribution was to lay the foundations of the theory of probability.

The fame of Pascal, however, rests only to a small degree on his scientific work. Both adversary and advocate, as the title of this book suggests, he employed his exceptional talents in the public pursuit of religious controversy (especially through the *Lettres Provinciales*) and the compilation of extensive notes (the *Pensées*) intended as the basis of *An Apology for the Christian Religion* which he did not live to complete. These works not only provide extraordinary insights into the human condition, but have had a great and lasting influence on French language and literature.

Yet his influence on probability was scarcely less; before his time, probability calculations amounted to no more than the enumeration of equally-probable outcomes in games of chance. Pascal introduced the important idea of manipulating expectations using recursively the fact that if expectations of gain X and Y are equally probable, the expectation is $\frac{1}{2}(X+Y)$. He also introduced the binomial distribution for equal chances and with its help, and that of mathematical induction applied to expectations, solved the Problem of Points for two players.

This problem was the topic of the correspondence between Pascal and Pierre de Fermat in the summer of 1654 which, together with Pascal's contemporary *Traité du Triangle Arithmétique*, includes not one but three solutions. Suppose two players stake equal money on being the first to win n points in a game in which the winner of each point is determined by the toss of a coin, heads for one player and tails for the other. If such a game is interrupted when one player still lacks a points and the other b, how should the stakes be divided between them?

On the evidence of the correspondence, Fermat and Pascal independently concluded that the problem could be solved by noting that at most $(a+b-1)$ more tosses will settle the game, and that if this number of tosses is imagined to have been made, the resulting 2^{a+b-1} possible games (each equally probable) may be classified according to the winner in each case, the stakes then being divided accordingly. Thus the real game, of indeterminate length, is embedded in an imaginary game of fixed length. Apart from this novel idea, however, such a solution by enumeration is straightforward, but Pascal offered both an independent method based on expectations which is valid for any number of players and, in the *Traité du Triangle Arithmétique*, the solution for two players in terms of the binomial distribution. This, now the standard solution, though derived from the solution by enumeration, was proved by Pascal by induction applied to expectations. The binomial distribution was not given algebraically but by reference to the "arithmetical triangle" of binomial coefficients, whose properties Pascal elaborated in his *Traité* (whence the name Pascal's Triangle).

An original result of Pascal's, given in the *Traité*, is the *combinatorial* proof of the fundamental relation

$$^{n+1}C_{r+1} = {}^{n}C_{r} + {}^{n}C_{r+1},$$

and this work also contains the first formal proof of the long-known binomial theorem for positive integral index.

Late in his *annus mirabilis* of 1654 Pascal suffered an intense religious episode which persuaded him to withdraw from society. Apart from some important work on the cycloid curve, he contributed nothing further of significance to mathematics. He died on 19th August 1662.

R.J. Nelson's book is an addition to the voluminous secondary literature on Pascal which will sit uneasily on a scientist's bookshelf. An examination of Pascal's psychology from the point of view of linguistic philosophy, it is itself written in a language that few will find easy. Thus:

> To be sure, with its emphasis on the nonapodictic notion of figure and its composition in fragments, this most famous work of Pascal [the *Pensées*] does seem to lend itself to a theory of language skeptical of verbal mimesis, to a catachresis suggesting, at least to Marin, that Pascal views all language as aporetic, disjoined from the things, either objects or immutable ideas, that a mimological view of language posits as the referents or signifieds of words or signifiers.

It will be a while before the author's insights into the workings of Pascal's mind influence our understanding of Pascal's science, and that may be a pity, for Part I ("The Adversary") of his book is both interesting and accurate where it touches on scientific matters; but when the Two Cultures are divided by a common language it is inevitable. ☐

A.W.F. Edwards is a Fellow of Gonville and Caius College and Reader in Mathematical Biology in the University of Cambridge. He has recently completed a book, Pascal's Arithmetical Triangle.

How to get off the MX hook

The US Congress has slapped the Administration in the face by denying funds for MX construction: the problem now, for all concerned, is to find a more manageable missile defence.

The Reagan Administration's defeat in Congress on the MX missile is humiliating but well deserved. Since President Carter's time, it has been understood between the executive and the legislative branches of the United States government that this expensive weapon would not be built until some way had been found of deploying it so as to give both generals and taxpayers some assurance that a substantial proportion of the missiles would survive a first attack from somewhere else. President Carter's favourite solution, shuttling missiles about a dedicated subway system, could have been effective if his Congress had not jibbed at the cost. President Reagan's high-tech solution of the same problem — putting missiles so close together that one attack will neutralize the next — is much more ingenious but even less credible (see *Nature* 2 December, p.389). People skilled at the assessment of the damage done by nuclear weapons say that they understand why "dense pack" should be safe, but acknowledge (as if it were a minor oversight) that they should have given other people more time to understand. What the US Congress has now asked is that if, with the benefit of all the briefings to which it has been privileged in the past few weeks, it cannot understand how dense-packed MX could survive, what reason is there to suppose that a hostile power (*any* hostile power) would be so persuaded of the inviolability of some part of an MX force that it would refrain from a first strike?

The same point bears even more directly on what congressmen's (or women's) constituents think about MX. If a missile-park in Wyoming should fall short of seeming to a potential enemy a viable retaliatory force, why should it seem a good investment of tax dollars to the electors in congressional districts? Congressmen (and women) have learned in the past few years, often against their predispositions, that nothing is as certain to crowd out a community hall, or a town square, than an invitation to protest against MX, or nuclear arms as such or, even, against nuclear things (such as nuclear reactors) in an even broader sense. Latterly, the federal government has been brought face to face with this sombre truth by the knowledge that there is a standing army of a quarter of a million people ready to fill the space around the Washington Monument whenever the call goes out for a protest against something nuclear.

So, in their small ways, congressmen (and women) are already individually paying a price for the MX and what is called its "basing mode". The chances are that even the federal government, a loose synonym for the Reagan Administration, will not be able to survive indefinite rebellion against an unconvincing case for nuclear reinforcement. The danger now is that if the Administration insists that its scheme for the deployment of MX is, for all its faults, the best that it can think of, it will merely widen the gulf between itself and those among its taxpayers who dissent. The Administration has to learn to live with its nuclear opposition.

The military have an important part to play in helping to square this essentially political circle. Many of those who disbelieve in Dense Pack do so because they know in their bones that the technical attributes of the MX missile are an impediment to more sophisticated means of deployment. The ideal, of course, would be that missiles such as MX should be made stochastically invulnerable to destruction from some other missile force by their mobility, and by the opportunities for deception that mobility provides. Putting missiles such as MX in ocean-going submarines may serve well enough for a counter-city force, but the accuracy is not great enough for a missile force intended to knock out other missiles. The simple resolution of this military dilemma, of course, is to acknowledge that MX (which will weigh at least 100 tonnes) is too big to be mobile, and that it would therefore be better to start from somewhere else — say an upgraded version of the submarine-launched Trident, the land-based version of which is known as D-4. Better still, why not go for a much smaller missile that need not weigh more than 10 tonnes or so — mobile enough to be carried on almost any kind of vehicle?

Politically, the US Administration cannot openly embrace such a solution. To embark all over again on the construction of another strategic weapons system would seem like vacillation to the voters and like weakness to potential enemies. Technically, however, there are viable solutions. It would be possible, for example, to build some extra submarines equipped with missiles so as temporarily to keep potential aggressors in their places. That arguments of this kind may have persuaded the Soviet Union, in the mid-1960s, to plan enormously to increase its deployment of strategic missiles is probably, in retrospect, irrelevant. What matters now is merely that the arms race has a curiously irreversible character. If one side builds a new strategic weapons system, the other is likely to follow suit and the result is likely to be a permanent increase of mutual striking power. Building a system like MX is hard enough, but dismantling it is even harder.

Hitherto, the fruits of negotiations on the limitation of strategic arms, such as those that have been taking place at Geneva for almost a year, have been negligible in comparison with what the arms manufacturers have accomplished. Technically, however, there is a way out even from that conundrum: settle for the ratifications of a few simple arms control agreements already negotiated, the threshold test-ban treaty, the agreement to prohibit except under tight controls peaceful nuclear explosions and even Salt II.

The moral, in short, is that if Congress will not give the Administration what it wants, a deterrent that is the opposite of credible in the sense that those who have paid for it do not believe in it, and if (which is not necessarily the case) it is impossible to start again, the Reagan Administration will have to acknowledge that there is no serious alternative to serious negotiations on arms control. As it happens, the Administration has been presented, in the Geneva negotiations on the limitation of intermediate-range weapons in Europe, with an awkward problem on which to brood over the Christmas vacation; the Soviet Union has offered to reduce the number of nuclear warheads based on SS-20 missiles to 300 if only the United States will refrain from putting Pershing II and cruise missiles on their allotted bases in Europe by the end of 1983, and also agree (which is impossible) that the United Kingdom and France should fall in with whatever the superpowers eventually decide. The terms offered are unacceptable not simply because they are unattainable but because they would also be inequitable; they are nevertheless the best prospect at Geneva for a year. The United States should recognize the offer as an opportunity to throw the theatre and strategic weapons negotiations together (where they belong), for winning some arms control agreement below present levels and for escaping from the MX hook.

Protecting basic research

The US administration plans a generous science budget. It must not look for quick returns.

Curious things are happening at the National Science Foundation, where the ebullient Dr Edward Knapp took over as director a few weeks ago (see *Nature* 11 November, p.100). The good news, or at least the advance reports thereof, is that the federal government's budget for the year beginning next October, to be published when the new Congress has convened in January, will ask the Congress to approve a substantial increase in the foundation's budget by about 18 per cent, well above the rate of inflation (now down to 6 per cent). This development seems to be but a part of the Administration's determination that whatever happens in the next year or two ahead, basic research will not be starved of funds. The principle seems to be that while systematically ridding itself of obligations to carry through further technological demonstration projects — Clinch River is an exception — on the grounds that industry itself should pay for potentially money-making projects, the Administration appears to have acknowledged its own continuing responsibility towards basic research. Other agencies than the foundation, the National Institutes of Health in particular, will now be anxious to find out if the Administration's new-found generosity applies to them.

The other side of the same coin is that the Administration is looking for results — prosperity and all that — but results that it cannot yet clearly define. The argument seems to be that if the Administration has been so good as to agree with academic scientists that basic research is ultimately the wellspring of industrial innovation, and has written its cheques accordingly, it is perfectly within its rights to ask that innovations should flow thick and fast once the cheques are in the mail — and preferably before the next election twenty months or so from now. In the circumstances, it is understandable that Dr Knapp should have been advised to get rid of the three assistant directors whom he inherited (see *Nature* 16 December, p.567); the well known phenomenon that new brooms are rendered ineffectual by the tired servants who use them (to mix a mixed-up metaphor) is in this case complicated by the Administration's need to know who will be responsible for what befalls in the years ahead. The changing of the guard at the foundation is, as of now, politic and not political; Dr Knapp, supported strongly by his previous colleague at Los Alamos, Dr George Keyworth (now the President's adviser on science and technology at the White House), is promising to change the world, perhaps even to break the mould or shift the paradigm; those who will be writing the cheques in the fiscal years ahead want to know who should be blamed if Dr Knapp fails to deliver.

Knapp's prospectus is startling not merely because of the promises it makes on behalf of basic science as the fountain from which innovations spring but because it acknowledges that basic research is educative. Only two years after having offended almost everybody in sight by deleting from the foundation's budget those line-items concerned with the support of science education (in translation, the equivalent of curriculum development in the 1960s mould), the Administration is about to go to Congress saying that the National Science Foundation has a part to play in the education of scientists but this time at a professional level, perhaps by means of partnerships between industry and universities that will be sweetened by modest support from the National Science Foundation. Some of the schemes now being canvassed in Washington are not very different from those tried out in the past decade by the Science and Engineering Council in the United Kingdom. If that is how the budget indeed turns out, the consequence will be that even the next administration (due to be elected in 1984) will not know what to make of Dr Knapp's promises.

What follows is what is called normative or prescriptive advice. Understandably but also rightly, Knapp is impatient that so little (in the way of innovation) has been accomplished by so much expenditure. Among such people, impatience is a virtue. Academic scientists, the foundation's chief pensioners, are almost wilfully indifferent to the needs of industry, their students obstinately persuaded that the academic life is best. A direct attack on these familiar conventions from somebody such as Knapp could help invigorate the system by means of which institutions of higher education train professional scientists. The result, with luck, could be not so much a spate of industrially relevant innovation as a modest cadre of able people. But none of these benefits would show up within what politicians would consider a reasonable time, and certainly not before the next election. More might be accomplished through the National Institutes of Health, which have at least a chance of understanding (not curing) cancer. So Dr Knapp must now keep talking (in public) about other people's opportunities in the hope that he will eventually be recognized as the man who made the National Science Foundation into what it should always have been — a low-budget agency with disproportionately large responsibilities.

Inventing the Wheel

The impending inquiry on nuclear power in Britain promises frustration.

Some years ago (to be precise, in 1972) the Central Electricity Generating Board, the only British public utility empowered to generate electricity for sale to commercial buyers, told a parliamentary committee of its hopes for the future of nuclear power generation. With electricity consumption increasing by seven per cent a year, or doubling every decade, and with the stagnation of coal output, it seemed natural enough that the board should rely for its future sources of energy on nuclear power and oil. (The last strand in the British fuel economy was cut in 1973, when the price of oil was multiplied by between three and four.) In 1972 the generating board was able, a little controversially, to announce that among the nuclear plants it planned to build would ideally be one fashioned on the principles laid down by engineers in the United States, in which the uranium fuel would be enriched to the extent of a few per cent in uranium-235 and in which heat would be carried away to steam generators by means of water under considerable pressure, perhaps 100 times that of the atmosphere. Next year, on 11 January 1983, a public inquiry will be opened in the country town of Sizewell in Suffolk so as to enable the British government to decide whether what is essentially a carbon copy of several hundreds of reactors built elsewhere should be built in Queen Elizabeth's fair isle. With a little luck, construction might begin fifteen years after the first intention was announced.

The inquiry is a public foolishness for which nobody can be excused. The chief culprit, however, is Mr Tony Benn, Minister of Energy in a previous British government who decreed that nothing should be done at Sizewell without a full inquiry. (The present British government weakly assumed Mr Benn's obligation at its election in 1979.) The Central Electricity Generating Board, which has steadfastly refused to confirm the obvious — that the inquiry is a waste of public money and a needless impost on electricity consumers — is almost as much to blame. For a single pressurized-water reactor is not in itself a hazard — and the best way of telling what the hazard would be if there were several such reactors is to build one of them in the first place.

None of this implies that the British government and the public monopolies that it franchises are neglectful of their duty; rather, the opposite is the truth. During the past three years, all those concerned have leaned over backwards to accommodate objectors to the proposed reactor, with the result that quaintly named organizations such as Friends of the Earth have taken to complaining that nobody will pay their expenses to travel in January from their headquarters (usually in London) to Suffolk (less than 100 miles away) to repeat the arguments for which they are already well-known. In much the same spirit might those used to the yoke or litter as a means of transporting heavy objects over uneven ground have petitioned the Roman Senate 2,000 years ago for funds with which to protest at the introduction of wheeled traffic on the newly paved roads.

Missile spin-off creates activity

MX research an ill-wind brings good

Washington

Research centres around the United States will benefit from President Reagan's determination to press ahead with the MX missile. As long as the fate of the 70-foot long missile and its method of deployment hangs in the balance, lots of money must be spent to keep the teams together and to work on the problems under debate.

At the time of going to press, Congress had effectively deleted $988 million for production of the first five MX missiles, and seemed likely to attach conditions to parts of the $2,500 million MX research and development budget. But most of this amount seemed likely to go forward, as would other parts of the defence budget that related to research, such as funds for Ballistic Missile Defense (BMD) research.

The Ballistic Missile Office of the Air Force pays out this money, most of it to prime contractors, to engineer and test the components of the missile. As with other major weapons systems, the MX's contractors are scattered around the country (often in the districts of important members of Congress).

The Ballistic Missile Office also buys research from other parts of the Air Force to work on the basic problem of what would happen in a Soviet attack and how many MXs would survive. The computers that explore these scenarios belong to the Strategic Air Command, but other offices, such as the Air Force's Office of Studies and Analysis (which judges the "military utility" of total weapons systems), do the analysis.

The "super-hardening" of silos is studied by the Defense Nuclear Agency (DNA), a separate Department of Defense agency whose job is to assess the effects of nuclear explosions. In 1982 DNA reported on a series of tests it had made of blasts over super-hardened silos, which showed they could survive. But the tests were made by combining ordinary explosives to simulate the blast of a 25 megaton nuclear explosion, which makes the conclusion suspect, according to Kosta Tsipis, director of the Massachusetts Institute of Technology programme in Science and Technology for International Security.

Two of the national laboratories, Lawrence Livermore and Los Alamos, are expert in the disturbed environment into which nuclear warheads must fly — and so study problems related to the MX basing mode too.

The Army's BMD programme is also gaining research funds as a result of the need to design a system that could defend the "dense pack" missile field. The BMD programme contracts with private universities such as Stanford, Carnegie-Mellon and the Georgia Institute of Technology.

Outside experts who oppose the plan, such as IBM's Richard Garwin, are few, but powerful. If the dense pack plan is rejected, as other, previous basing modes have been, it may be because the research that underpins it is so scattered.

Deborah Shapley

Dense pack logistics

On 22 November, the President submitted a "dense pack" basing proposal for the new MX missile to Congress to persuade it to release $715 million for research on basing modes in the budget for fiscal year 1983 then being finalized. The plan would put 200 of the highly accurate missiles into a 20-square mile area, at an Air Force base in Wyoming, in silos that would be "super-hardened" so as to withstand a massive pressure of 100,000 pounds per square inch. The MX missiles would be packed 1,800 feet apart, so that incoming Soviet warheads would have to burst near each other and destroy one another through a phenomenon known as fratricide. The Air Force, which runs the MX programme, argued that at least 100 MXs in their silos could survive an all-out Soviet attack; because they would be left to retaliate, the Soviet Union would not attack in the first place.

But many in Congress, including conservatives usually supportive of President Reagan's defence programme, attacked the plan. Bolstered by advice from outside experts, they doubted whether the Air Force could so suddenly have discovered "superhardening", or that fratricide would really occur, or that dense pack would survive exotic methods of attack, such as having the warheads dig up the ground. Moreover, the Air Force admitted that the survivability of dense pack would ultimately depend on building a ballistic missile defence system, something the United States and the Soviet Union virtually renounced by treaty in 1972.

The House voted by 245 to 176 to delete production funds for the missile: the Senate approved the production funds but with a condition that they not be spent until the dense pack plan and the alternatives had been restudied and submitted to the next Congress. The net effect was correction Congress' action was the first serious rebuff to the President's ambitious defence programme. Deborah Shapley

US Congress cops out

Washington

The lame-duck Congress went out with a whimper, not a bang, this week, having failed to act on any of the many science- and technology-related initiatives brought before it this year.

The last hectic hours of the session were taken up with marathon all-night and weekend efforts to agree on a stop-gap bill to keep the government running until September 1983, the end of the fiscal year. The bill that finally emerged from the full Congress, after repeated delaying tactics by Senate opponents of one or another of its provisions, does the following:

- **Clinch River breeder reactor.** $181 million has been provided to keep this controversial project alive. But opponents, who last week thought they had finally delivered Clinch River a death blow when the House of Representatives voted its funds, did win a freeze on construction and a study of the project's usefulness.
- **Regulation of doctors.** The House-Senate compromise knocks out a rider by the American Medical Association that would have barred the federal government from investigating and regulating the trade practices of doctors and other professionals. The amendment had passed the House, but not the Senate.

The science- and technology-related bills left to die include:

- **Nuclear waste disposal.** The United States still has no comprehensive plan for the construction of a permanent repository from commercial nuclear waste or for the interim storage of spent fuel. A legislative initiative in the last Congress, two years ago, was also killed off at the last minute.
- **Immigration reform.** This legislation would have imposed new restrictions on the employment of foreign students after their graduation from US universities. The bill was defeated in the House largely due to opposition from Hispanic groups concerned about its other provisions.
- **Animal rights.** This bill would have required laboratories receiving federal research funds to upgrade their animal facilities and institutional controls on the use of animals in research. The National Institutes of Health may however adopt some of the bill's provisions anyway.
- **Clean Air Act.** A two-year effort to reauthorize the basic air pollution control law and to add new provisions for the abatement of acid rain failed to get out of committee. The present statute remains in effect.

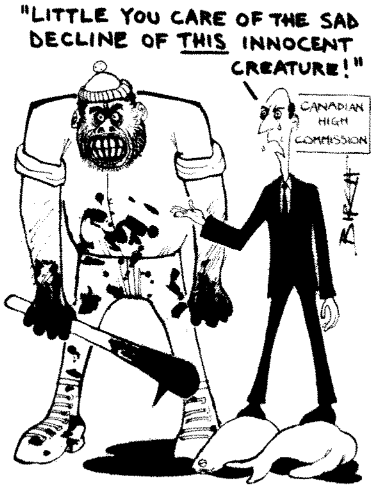
Canada's seals

Who's cooking what books?

The toughly worded resolution approved by the EEC's environment ministers last week to introduce a ban on the import of seal pup skins by its member states comes amid growing concern that the government of Canada (the country most affected by the ban) is making improper use of scientific data to support its opposition.

The relevant scientific questions concern trends and sizes of stocks of harp seals and hooded seals. A recent statement by the Canadian Fisheries and Oceans Minister Pierre de Bané that an October report by an *ad hoc* working group of the International Council for the Exploration of the Sea (ICES) took a "neutral position regarding the hooded seal herd" is described in an EEC memorandum as "utterly wrong and totally without foundation", and catch figures quoted by Mr de Bané are described as "wrong". As to the harp seal, the ICES conclusion — cited in a Canadian government advertisement — that stocks in the north-west Atlantic probably increased between the late 1960s and the late 1970s has since been put down to statistical artefact by several experts.



"LITTLE YOU CARE OF THE SAD DECLINE OF THIS INNOCENT CREATURE!"
CANADIAN HIGH COMMISSION

An attempt three weeks ago by the EEC Environment Council to reach a decision on the proposed ban foundered amid confusion over what legal instrument should be used and what paragraph in the Treaty of Rome should form a basis for the decision. Enthusiasm for the ban ranged from lukewarm (United Kingdom) to fervent (the Netherlands and Italy). The resolution finally approved, unlike a regulation or a directive, is flexible and is not legally enforcible.

Since the abortive meeting of three weeks ago, the Canadian government has placed advertisements in daily newspapers in several European countries claiming that the ICES report, which has been commissioned by Canada and the EEC, "unanimously reported that the harp seal stock of the North West Atlantic has grown significantly during the past decade." According to one scientist whose work formed an integral part of the ICES review, this conclusion "simply isn't there".

The ICES report estimated stocks of harp seals in the late 1960s at 1.2–1.6 million, while in the late 1970s the estimate is 1.5–2.0 million; it says, however, that the possibility that the herd had in fact decreased over this period was "not negligible". It is now thought that the suggestion of an increase is due entirely to a statistical artefact resulting from an attempt to compare estimates based on different methods.

On the question of the much less numerous hooded seal, the advertisements say "there is no indication that this species is in any way endangered". This contrasts sharply with an earlier study commissioned by the EEC from the British Nature Conservancy Council (NCC), which concluded that there was a risk that both species would be endangered by a continuation of the present rates of exploitation, with the hooded seal being most at peril. The ICES report in fact concluded simply that insufficient data are available to provide estimates of hooded seal stocks. Dr Sidney Holt, vice-chairman of the International Union for the Conservation of Nature and Natural Resources, himself a marine mammal specialist, has described the Canadian claims as "gross distortions" of the study's conclusions.

Mr Brian Casey, First Secretary at the Canadian High Commission in London, said of the NCC study that the conclusions were swayed by bias and that anyway it was invalidated by the ICES study. A Canadian government document also describes the NCC study group as "completely dominated by dedicated opponents of the seal hunt" and says NCC is "flagrantly selective" in its use of data. But the two scientists who drafted the NCC report also sat on the ICES working party.

The questions considered by the NCC and ICES reports were substantially different, and there are in fact few actual points of disagreement. The NCC report considered long-term changes in the total stocks of both species, whereas the ICES report was confined to short-term trends in stocks in the north-west Atlantic. The ICES report actually supports NCC's finding that there is a severe shortage of data on hooded seal stocks, which makes reliable estimates of population sizes impossible. It now appears that it ought also to agree with the NCC's conclusion that it is uncertain whether harp seal stocks are increasing or declining. But all this uncertainty may soon be cleared up. The Canadian government is advocating an International Convention on North Atlantic Sealing to provide for expert study and management of all aspects of the seal hunt. **Tim Beardsley & Jasper Becker**

Migrant academics

Mobile Harvard

Washington

Last week, Harvard physicist Sheldon ("Shelly") Glashow, who shared the 1979 Nobel prize, denied widespread rumours that he had been offered a job at Texas A & M university at College Station at an annual salary of $250,000. But Glashow did say he was considering moving there, had visited the university and looked at property. His wife has also visited. Clinton A. Phillips, dean of the faculty at Texas A & M, confirmed that "we are in a negotiation phase" with Glashow, who may spend a year "to see how he likes it".

Glashow would be a catch for the university, which sits on the prairie more than 100 miles from Austin and 90 miles from Houston. Twenty years ago, it had 10,000 students and not a strong reputation. But the state had set aside land in West Texas to help provide for the school, and, like other land in Texas, it had oil under it. So in the 1970s, while the endowments of other, better-known universities shrank, this permanent fund that serves Texas A & M and also the University of Texas at Austin, climbed to $1,700 million —comparable with Harvard's endowment.

Texas A & M has recently lured a new dean to the college of science, John Fackler, a chemist from Case Western Reserve, and provided him with funds for laboratory facilities and staff to continue his research there. Arthur Hansen, formerly president of Purdue University, started as chancellor of Texas A & M last July and was provided with a new home which, Phillips said, cost almost $1 million.

Phillips believes history as well as money is on his side. "In the beginning in this country there was the Ivy League. Then other universities came to be stars: the University of Chicago, Berkeley and Stanford grew in stature. Now our time has come".

Two things have clouded what otherwise seems to be a case of honest academic piracy. The first was that the university's interest in Glashow became known after it hired a new football coach for a comparable figure including television rights and other benefits. The president and chancellor received rises soon after, just to keep their dignity, so to speak. Nonetheless, the new coach had a bad season.

Texas A & M's arch-rival in football is the University of Texas at Austin, which is entitled to two-thirds of the benefits of the permanent fund. In talking to Glashow, Texas A & M may be trying to rival Austin in physics, too. In January 1982, Steven Weinberg, also a well-known Harvard physicist with a Nobel prize, decided to move to the Austin physics department, rejoining his wife, a professor of law, who in 1980 had joined the faculty of the Law School of the University of Texas at Austin. Weinberg's salary is rumoured to

0028-0836/82/510674-02$01.00

be $110,000, but he will not confirm this, saying only that his salary is not all that much higher than it was at Harvard.

The university is also giving him an appointment in astronomy and the chance to hire additional faculty to build up the physics department, which he considers excellent in some areas. "It's a very exciting prospect of being able to build a good group", he says. "I don't believe scientists go anywhere for money."

Deborah Shapley

French nuclear power

Cap de la Hague heads on

The French government has finally approved a major extension of the nuclear fuel reprocessing plant at Cap de la Hague, near Cherbourg on the English Channel coast. Meanwhile, a major and partly critical report on La Hague and on reprocessing in general remains unpublished.

The extension will cost some FF20,000 million (£1,786 million) and covers the upgrading of the existing UP2 400 plant to handle 800 tonnes of spent pressurized water reactor fuel and the construction of a completely new plant (UP3) to handle the same amount. The plants would handle French spent fuel and that arising from plants in Japan, West Germany and Belgium with which the French fuel company Cogema already has contracts. Without the extension, the French nuclear power programme would have been compromised. But UP2 400 has been notoriously ineffective — reprocessing only 250 tonnes in its first five years compared with its projected 2,000. After a series of accidents, one of them potentially disastrous (see *Nature* **290**, 538; 1981), the present government set up a scientific commission to investigate the plant.

The report is now complete and should be published in mid-February — but the government has announced that the expansion of La Hague should go ahead before the report is out.

The commission's conclusions, although not public, are believed to be broadly in line with remarks communicated by Professor Castaing, its chairman, to science minister Jean-Pierre Chevènement in April. These were that while Cogema and the Commissariat à l'Energie Atomique now "have the know-how" to build the extension, the technology is only sufficient "for the short and medium term". Castaing told Chevènement that the most satisfactory solution would be "better waste treatment", in particular the isolation of neptunium and americium from the high-level waste stream. The chairman also argued that long-term storage of unreprocessed spent fuel, either wet or dry, was feasible, safe and economical, and must be studied because part of the spent fuel to which France is now committed might remain unreprocessed (if there were problems with the new plant for example). The commission also advocated work on final disposal for glassified waste forms and spent fuel itself. And he added that a fast breeder programme "implies substantial progress in reprocessing". These remarks may have stimulated the government to a preemptive announcement of the La Hague extension.

Robert Walgate

Martlesham in business

An important new semiconductor manufacturing process that was originally developed at British Telecom research laboratories is now being exploited commercially by British Telecom's offshoot, Martlesham Enterprises Ltd, together with Thomas Swan and Co. Ltd.

In January this year British Telecom set up in partnership with other investors to exploit a new process developed by Dr M.M. Faktor and Dr R.H. Moss at British Telecom's laboratories at Martlesham Heath. The process uses a new series of compounds developed in association with Professor D.C. Bradley at Queen Mary College, London, in a technique known as metallo-organic chemical vapour deposition (MOCVD). Existing techniques for MOCVD which used highly toxic and explosive trialkyl gallium and indium compounds had proved extremely hazardous, and had caused several fires and explosions.

The new chemicals will avoid the use of these dangerous compounds and will also increase the range of applications of the method. In particular the process can now be carried out much more effectively with indium phosphide, a material which is likely to find increasing applications in semiconductor devices which emit and transmit infrared light; connected to optical fibres such devices will be important in long-distance optic information links.

Martlesham Enterprises, after a long search, has now awarded manufacturing and selling rights for the new process to Thomas Swan, a specialist chemical manufacturer, which has already secured advance orders for the new chemicals and process equipment from the Massachusetts Institute of Technology.

Tim Beardsley

Soviet science policy

Spread the net

Softly, softly, decentralization and increased local responsibility are emerging as major themes in President Yuri Andropov's economic policy for the Soviet Union. The annual meeting of the Academy of Sciences of the USSR earlier this month suggested that that decentralization should also apply to science. Matching words to good intentions, coverage of the session in the official party newspaper *Pravda* concentrated not on the speech of the academy president, Academician Anatolii P. Aleksandrov, but on that of one of the vice-presidents, Vladimir A. Kotel'nikov, which emphasized the role of the "Republic" academies and the local filials of the All-Union academy.

The occasion coincided with the celebration last week of the 60th anniversary of the founding of the Soviet

INSERM's new shape

French medical researchers are to be subjected to a new form of scientific assessment next year — a mixture of stricter and looser rules than those they face at present.

The new arrangements are part of the long-awaited reform of the Institut National de la Santé et de la Recherche Médicale (INSERM), a reform delayed by arguments over whether directors of research groups should have terms limited to 12 years. That question having been settled — the limit will apply, but not immediately — the way was open for official approval of the full reform. That approval has now been granted, and the details of the reform were published last week.

Among the terms are the new forms of scientific assessment, dear to the heart of INSERM's innovatory director-general, M. Philippe Lazar. Lazar has sought a system which would allow non-conformist — and perhaps superficially mediocre — groups to make their mark. He believes talent, particularly in the undervalued sciences, must be given its opportunity, but that judgements, when made, must be strict and scientific.

The reform meets these two objectives. Groups will be judged infrequently (probably less than annually) but firmly by specialist scientific commissions — which must visit the laboratory concerned. The result will be the definition of a research programme, against which the group will be assessed next time round, with a guaranteed long-term budget.

The mechanism will give groups more freedom and more time from pointless form-filling and fund-hunting, Lazar believes. Robert Walgate

0028-0836/82/510675-02$01.00

Union as a federal state. (The exact anniversary falls on 30 December.) Formally, Soviet culture is defined as "national in form and socialist in content", although what this means for science is not always easy to say, particularly since the implementation of the "Kruschchev theses" of 1958 which emphasized Russian as the preeminent language of Soviet scientific communication and thus blurred the individuality of such distinctive developments as the "Ukrainian school" of cybernetics of the early 1960s. Some local institutes have, however, achieved international renown, notably the Paton Institute of Electric Welding (Ukraine), the Institute of Astrophysics and Atmosphere Physics (Estonia), the Byurakan Astrophysics Observatory (Armenia), and the Tien Shan Cosmic Ray Station (Kazakhstan). Their reputations, however, derive from their status as representatives of Soviet science rather than of the republic academies to which they belong.

In creating these academies, from the Ukrainian Academy founded in 1919 to the Moldavian in 1961, the Soviet state was following the federal structure of the Soviet Union which formally says that all 15 union republics are fully autonomous. (Significantly, though, the largest republic of all, the Russian Socialist Federative Soviet Republic (RSFSR), has no academy of its own, being presumably well served by the All-Union academy.)

The propaganda value of separate republic academies is clear. In his jubilee speech, Academician Kotel'nikov reiterated the usual half-truth that the Estonian Academy of Sciences was established in 1945, in the process ignoring the 1938 decree of the then independent Estonian Republic setting up that academy.

Recently, there has been an increasing emphasis on the duty of scientific institutes to service local industry. In the remoter areas of the far-flung RSFSR, former research stations have been upgraded into fully-fledged filials of the Soviet Academy of Sciences.

This theme of regional devolution has been evident since before the death of Leonid Brezhnev and the accession of Yuri Andropov as General Secretary of the Party. The media run-up to the jubilee had begun to stress the links between the republic academies and local production. In particular, the influential weekly *Literaturnaya Gazeta* ran a survey in which the presidents of the 14 republic academies were asked to describe some of the most interesting research carried out by their academies, the main difficulties they encountered and the participation of the academies in the present high-priority food programme. The answers concentrated overwhelmingly on local needs — from the use of lasers for environmental monitoring in Lithuania to soil surveys for new vineyards in Azerbaijan. **Vera Rich**

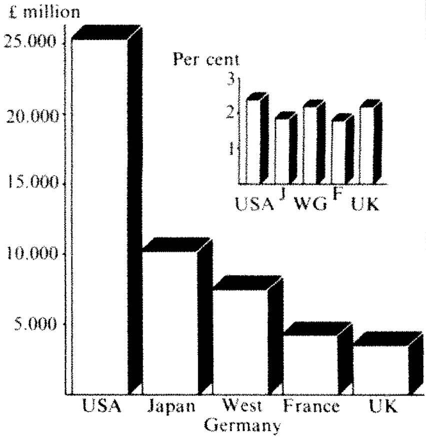
British research policy

Could do much better

Lack of confidence among would-be innovators was cited last week as a major problem underlying Britain's industrial malaise, by Sir Henry Chilver, chairman of the Advisory Council for Applied Research and Development (ACARD). Sir Henry, who was addressing the Parliamentary and Scientific Committee (an unofficial group of MPs, peers and representatives from industry), stressed the importance of science research and development for Britain, and emphasized the need for effective coordination of policies in the many government departments involved with science and technology.

ACARD's terms of reference were broadened in July and the council is now well placed to play a significant role in coordinating research and development efforts in government and industry. ACARD reports directly to the Prime Minister and will also be advising in the recently announced annual reviews of research expenditure by government departments. Its new role was the result of the government's response to the report on "Science and Government" of the House of Lords Select Committee on Science and Technology, which recommended the appointment of a minister at Cabinet level to speak for science and technology.

Sir Henry pointed out that Britain's expenditure on research and development, while comparable with that of its competitors in terms of percentage of gross domestic product, represented only 7 per cent of the total spent in the five major industrial nations (see figure). He therefore argued for more spending on research in private industry and a greater concentration of resources in areas with a potential for later exploitation. He also suggested that more ideas from defence research should be taken up.



Total and relative expenditure on research and development in the five major industrial nations. Relative expenditure is given as a percentage of gross domestic product.

The primary problem, he said, was one of attitudes, and links between universities and industry should be fostered to encourage academics with good ideas to seek support for commercial development.

Few are likely to disagree, but it is far from certain that university researchers and financial institutions will take notice.

Tim Beardsley

India's second taste of Antarctica

Lucknow

The search for a suitable site for a permanent manned research station is the most important task for India's second scientific expedition to Antarctica. Almost exactly a year after the country's first expedition, the 28-member team set sail on 2 December aboard the hired Norwegian vessel *Polar Circle*.

As with the first mission, the landing site is to be near an old campsite at 70° 3′S/40° 7′E, named Dakshin Gangotri (Dakshin — south: Gangotri — the source of the River Ganges in the Himalayas). An automatic weather recording station has been operating there for the past year and the team's first task will be to collect a cassette of weather data.

The present expedition — under the leadership of Dr V. K. Raina, a glaciology expert from the Geological Survey of India — is due to stay on the ice for 60 days, compared with the 10 days of the first mission. Intelsat telex and telephone links have been set up to maintain contact with India's National Institute of Oceanography in Goa and the Department of Ocean Development (DOD) in New Delhi. DOD's link with Antarctica is particularly strong, since the head of the first Antarctic expedition, Dr S. Z. Qasim, is now Secretary of DOD.

With plans to have the permanent base operating by 1985, and ambitions either to build or to buy a research vessel of its own, India's interest in Antarctica is obviously growing. India has not yet signed the Antarctica Treaty. Prime Minister Indira Gandhi said in Parliament recently that her government is examining the case for signing the treaty, and she stressed that the implications for all developing countries are being considered.

India is taking part in discussions with other developing countries about joint efforts to explore and exploit Antarctica. However, offers of help from the Soviet Union, which offered the use of Soviet airstrips and buildings on the ice cap, have been turned down.

Zaka Imam

Nuclear reactor safety

Super-Sara's fate undecided

Brussels

Community ministers have again failed to reach a "final" decision on the Super-Sara project at the Joint Research Centre at Ispra in Italy to experiment with loss-of-coolant situations in nuclear reactors. Ever since the project was first proposed after the accident at Three Mile Island in the United States, the Community has procrastinated (*Nature* 11 November, p.99), letting the cost of the project soar.

At last week's meeting, the United Kingdom and West Germany again refused to be placated by Commissioner Etienne Davignon's promises to keep the project within the current estimates of 293.9 million European currency units (ECU) (£161.7 million) up to 1988. Vicomte Davignon, the European Commissioner for Energy and Industry, made a passionate appeal, arguing that it would be irrational to cancel the project when attempts should be made to reassure public opinion over nuclear energy. He recalled that the Western economic summit at Versailles agreed to promote international research into nuclear safety and that there was a danger that, if EEC halted its project, the United States would be unwilling to pass on its own research results.

Davignon held that continuing with Super-Sara would not need extra money apart from an extra 13 million ECU for each year between 1984 and 1987. The extra 27.5 million ECU needed for 1982 and 1983 could be found by transferring resources from another part of the budget. And he thought that by reducing funds for other research at the Joint Research Centres, half of the 39 million ECU needed for the three following years could be found comparatively easily.

The United Kingdom and West Germany were not impressed by this financial juggling and asked whether such a large sum of money might not be better employed in some other way.

The upshot is that a panel of three wise men, independent experts from Denmark, France and West Germany, will review the budgetary estimates and assess the value of the Super-Sara project in comparison with that of similar projects elsewhere. Their report, to be presented at the next research council meeting on 8 February, will also take into account the British delegation's suspicion that Super-Sara will absorb too many of EEC's nuclear scientists in an experiment concerned with coping with an emergency rather than on the prevention of disaster.

In the meantime, the European Commission is to think about alternatives for Ispra if in the end the Super-Sara project is cancelled. **Jasper Becker**

Interferon in France

Trial condemned

Paris

Professor Georges Mathé, a well known cancer researcher from the Paul Brousse Hospital at Villejuif, has publicly described as incompetent French doctors involved in preliminary trials with interferon as a possible treatment for cancer. He has criticized the method of administration and the dose and has asked for more information about the circumstances in which four patients involved in the trials died (see *Nature* 11 November, p.97). Mathé has also attacked the establishment where the trials took place and has even asked for the resignation of the members of the scientific council which was set up to monitor the experiments. As a result, the council and IPP (Institut Pasteur Production, the subsidiary of Sanofi–Elf–Aquitaine that produces the interferon) published information about the trials in November. More recently, in a confidential letter addressed to two journalists, they advised wariness of the aggressive tone of Professor Mathé's remarks, which could bring clinical trials of interferon and even clinical trials in general into disrepute.

Two of the four deaths were from myocardial infarction and another has been tentatively attributed to the same diagnosis, but nobody yet knows for certain what caused them. Professor Flamant, president of the monitoring council, says that it is necessary to keep an open mind about the possible role of interferon. But according to Dr Denis Pouillard, clinical physician at the Curie Foundation who participated in the trials, there was a marked similarity between the symptoms and those he had seen ten years earlier in patients given infusions of leukocytes that had been conserved in poor conditions. Dr Pouillard draws attention to the fact that IPP stores its interferon preparation at 4°C whereas -20°C is generally used for leukocyte interferon storage. He also says that since interferon made up only 1 per cent of the protein in the IPP preparation that was injected, it is likely that proteins other than interferon caused the toxicity.

The accidents gave strength to the supporters of gene splicing methods to produce interferon, which give purer and cheaper products. Professor Flamant, Dr Pouillard and Professor Falcoff at the Institut Curie, who is working with gamma-interferon, all advocate that both methods should continue and their products should be compared simultaneously. They would like to see an international body created to compare clinical trials with different kinds of interferon. At the moment, IPP is performing toxicity trials with the suspect interferon and with a tenfold purified derivative. If they show that the purified leukocyte interferon is innocuous, clinical trials will begin again, perhaps in January. **Isabelle Trocheris**

Toxic wastes blow

Brussels

One of the European Economic Community's hardy perennials has reappeared at the latest meeting of the Environment Council, the battle between the methods used on the mainland of Europe and in Britain for calculating the degree to which industrial discharges of toxic wastes should be restricted. Last Christmas, the British persuaded their partners to include in the directives regulating the discharge of toxic substances into water the "quality objective" method as well as the more strict "limit value" system. The latter sets fixed limits on discharges while the former relates the regulations to the use to which the environment concerned is put.

In the first directive, dealing with mercury, the British conceded that whichever system is used, all new plant must use the modern and effective pollution control equipment.

The second directive deals with cadmium discharges, and the French have been pressing for the British to agree that only limit values should be applied to regulations dealing with new plant. The British claim, however, that this breaks the compromise agreement reached last year.

The issue has now been referred back to Coreper, the committee of the member states' permanent representatives, for further discussion, a considerable setback for the Commission. **Jasper Becker**

Jojoba oil

Too late now?

Commercial interest in jojoba oil, once heralded as a substitute for sperm whale oil but since discredited largely because of cost, could be rekindled by a tissue culture technique being developed at Twyford Plant Laboratories in Somerset.

The high price of the oil is largely a reflection of the problems of cultivating jojoba plants. Only female plants produce the oil-yielding nuts and only a small proportion of plants provide a high enough yield of oil to be of commercial value. Attempts to develop the vegetative propagation of high yielding plants have failed because jojoba does not grow well from cuttings.

Now, however, Twyford — part of International Plant Laboratories — and other groups in Israel and the United States have developed a successful approach to propagation by culture of the jojoba's meristem — the growing tip of a shoot or root. The meristem is grown on a series of nutrient media until a seedling develops from it. The seedling is then split into two

0028-0836/82/510677-02$01.00

or more parts each of which is grown into a complete seedling. By repeating the process a large population of genetically identical plants is produced. And if the starting meristem came from a plant of high oil yield, the population derived from it by meristem culture should also be high yielders.

Twyford has already shipped clonal populations of jojoba to Arizona for field trials, but admits that the project is still in its infancy, not least because there is a five-year time lag before a plant bears its first crop of nuts.

Even if everything goes according to plan and jojoba oil becomes available at a low price, it is by no means certain that there will be a market for it. According to Highgate and Joab, a major sperm oil refiner now concerned with the development of substitutes, had jojoba oil been available when sperm oil was withdrawn from Britain and the United States, its market would have been assured because it could have replaced sperm whale oil in nearly all of its diverse uses. But industry has since become accustomed to using different oils for different processes and today's market will simply judge whether jojoba oil is better than any of these oils for a particular application. The most likely future for jojoba oil now lies in small specialized fields where no other reasonable alternative exists. **Melanie Kee**

Cancer prize

Washington

The Hammer Prize Foundation has awarded its first $100,000 prize for cancer research to Dr Ronald Levy of Stanford University and George Stevenson of the University of Southampton (in Britain). They were cited for their work on monoclonal antibodies in the treatment of B-cell leukaemia and lymphoma.

The prize, which will be awarded annually for ten years, was established by Armand Hammer, the chairman of Occidental Petroleum. Hammer has offered an additional $1 million for a "cure" for cancer similar to the cure for polio achieved by Dr Jonas Salk. The annual prizes are for the scientists who have made the "greatest contribution towards a cure".

The prize has stirred a certain amount of controversy, both for its origins and for its terms. Some researchers question its focus on treatment, rather than basic research, saying that such an emphasis encourages "premature jabs". And there has been grumbling, too, about Hammer's ties with Occidental, the parent company of Hooker Chemical of Love Canal fame. Hammer's appointment to head the President's Cancer Panel — previously a panel of medical experts — had earlier provoked similar criticisms. Stephen Budiansky

Chemical toxins

USA and UN disagree

Washington

The issue of the use of Soviet toxic weapons in South-East Asia remains disputed. While the US State Department continues its campaign to convince sceptics that Soviet toxin weapons have been used in Afghanistan and South-East Asia, a long-awaited report by a United Nations (UN) group of experts has provided only inconclusive findings.

The most dramatic pieces of evidence now produced by the State Department are two Soviet gas masks obtained in "clandestine operations" in Afghanistan. According to the US Army Chemical Systems Laboratory, which analysed the masks, traces of several trichothecene mycotoxins were found on the surfaces and hose connections of the masks. These fungal toxins are said by the State Department to have been used extensively in Laos and in Kampuchea, where "yellow rain" attacks were first reported.

The State Department has also released analyses of blood, urine and tissue samples from 33 alleged victims of toxin attacks; trichothecenes were found in 16 of the subjects. "The finding of T-2 toxin and HT-2 toxin (a metabolite of T-2 toxin in animals) in the blood, urine and tissue of victims of these attacks provides unequivocal evidence of their use as weapons", the State Department concludes.

But in its report to the UN Secretary-General, the group paints a far more complex picture. Most striking is the utter confusion that the group found in refugees' reports of attacks and claimed illnesses. Two Hmong refugees who said they developed a rash after a chemical attack two weeks earlier were found on examination to have three-month-old fungal infections. Some others who attributed their illnesses to chemical weapons were found to have malaria, or in one case, a gastric ulcer. The group also found discrepancies in reports of numbers of fatalities, the colour of the agent said to have been sprayed and the timing and seriousness of the effects. The group's work had, however, been complicated by the denial of access to Laos and Kampuchea and was limited to interviewing and examining refugees who had crossed into Thailand long after the alleged attacks took place.

The most the UN group was willing to concede was that there is "circumstantial evidence" for the use of "some toxic material" in the areas of Laos inhabited by the Hmong. The group found stories of chemical weapons use in Afghanistan less believable, attributing reports there to incendiary weapons (which would give off irritating smoke as a by-product of combustion) and to a harassing agent such as adamsite. And reports of rapid decomposition of the bodies of chemical attack victims — which have been given prominent attention by the State Department — were "difficult to reconcile with known facts about the effects of chemical warfare agents or other chemical compounds".

Chemical analyses performed for the UN study were likewise inconclusive. Two of the laboratories that analysed blood and leaf samples from Thailand were unable to detect any trichothecenes — even in a control sample spiked with the compounds. A third laboratory reported trichothecenes in all samples submitted, including a blank control.

Furthermore, the possibility of cross-contamination of samples is always present; in addition, the identification of trichothecenes is to some degree a function of the analyst's experience and judgement.

The State Department has tried to avoid argument about its analyses by sending samples to Dr Chester Mirocha, a leading authority on the analysis of trichothecenes. Mirocha's technique is to react samples with trifluoroacetic acid; this produces volatile derivatives of trichothecenes that may then be separated by gas chromatography (GC) and analysed by mass spectrometry. A combination of the GC retention time and the mass-spectrometer peaks can provide "certain" identification, Mirocha says, with a detection limit of less than one part in 10^9. The blood and tissue samples that he analysed contained trichothecenes in the range 10–100 parts in 10^9.

Mirocha points out that even among workers in laboratories with a great deal of experience, quantitative results of trichothecene analyses can vary by as much as 30–60 per cent; in experienced laboratories the variations would not surprisingly be much greater, he says. "Some people have come into this entirely cold. Just because they're chemists doesn't mean they can automatically analyse for trichothecenes", says Mirocha. The UN group used laboratories at the Tokyo University of Science (run by Dr Y. Ueno, who, along with Mirocha, is considered to be one of the world's experts), the University of Veterinary Medicine in Vienna, and the Technical Research Centre in Espoo, Finland (see *Nature* 16 December, p.569).

But reliable as Mirocha's analyses may be, several independent experts question seriously what exactly he has been analysing. The gas masks, for example, were first analysed at the Army's laboratory; Mirocha was sent only a chloroform extract and asked to confirm the presence of T-2. Mirocha says he was also sent a piece of rubber or plastic on which he was unable to detect any of the toxins.

The State Department refuses to say how the masks were obtained, and independent verification of their origin and handling is clearly impossible. Gary Crocker, an intelligence analyst for the State Department, did say that they were obtained in "clandestine" operations specifically planned to obtain evidence of the use of chemical and toxin weapons. One mask was removed from a dead Soviet soldier in Afghanistan in December 1981; the other was obtained in Kabul, Afghanistan, in September 1981. Crocker says "the people who got it were instructed on how to handle it", and were provided with a similar sample container that would prevent contamination. "Things were handled properly all down the line".

Dr H. Bruno Schiefer, who conducted a study of toxin weapons use in South-East Asia earlier this year for the Canadian government (a study that found effects that could not be explained by "naturally occurring phenomena"), says "It doesn't really matter who" provides samples — the results "still don't stand up in court". Schiefer says "we would need some sort of verification" by scientists who could go into the affected areas, collect samples and bring them back for analysis.

Stronger criticism comes from Arthur Westing of Hampshire College. "The US has a long history of doctoring evidence", he says. "I don't know if the State Department is lying, but they haven't come close to proving their case." Westing says that "the most elementary mistake they made" was not to get blood and urine samples from a control population outside the area where toxins were allegedly sprayed. The parts-per-billion levels of trichothecenes found in the medical specimens from alleged victims may, he says, reflect natural exposure to the toxins: "There's no question that the *Fusarium* fungi that produce these toxins do occur in that region. The *Fusarium* fungus responsible for T-2, for instance, was described in the 1930s as occurring in Vietnam, according to Westing. And Westing points out that aflatoxin, well known to contaminate food, was found in one of the alleged victims at a concentration comparable with that of T-2.

Mirocha counters that his experiments with cows show that relatively large amounts of T-2 — hundreds of milligrammes — have to be ingested before it shows up in the blood at even the 10–100 parts in 10^9 level. "To say it's present endemically in the food is absurd", he says.

The State Department, for its part, seems less concerned with technical details than with the overall pattern of evidence. "I could take any piece of evidence and give you an alternative hypothesis", Crocker says, but the "strength of the case" lies in the agreement among reports from refugees and defectors, intelligence information and laboratory analyses. That argument is not likely to convince many sceptics; definitive proof may come only when an independent group of experts is allowed into Laos and Kampuchea.

Tasmanian environment

Dam threatens wilderness

Canberra

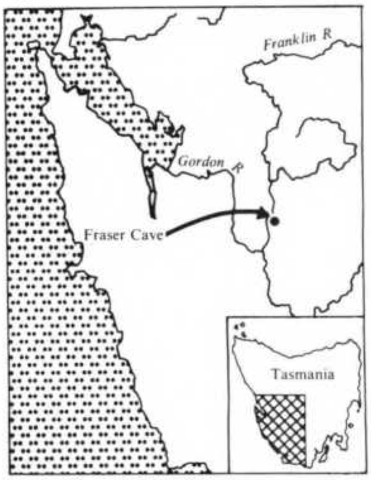
An area rich in archaeological sites from the last ice age will disappear beneath a flood of water as part of a hydro-electricity project unless Australia's national government overcomes its reluctance to interfere with a state decision. Last week Unesco's World Heritage Committee, meeting in Paris, placed the Western Tasmania Wilderness National Park on its register, thus increasing the pressure on the Tasmanian state government to reconsider its plan to build a dam on the Gordon River, just below its confluence with the Franklin River. The dam would inundate 37 kilometres of the Gordon, 37 kilometres of the Franklin and part of all the tributaries of the Gordon including all the recently discovered archaeological sites.

The national government is now left in a curious position. In November 1981 it backed the then Labour state government in applying to put the national park on the heritage list. When a newly elected Tasmanian government later decided to allow the Tasmanian Hydro-Electric Commission to build the dam the national government came under pressure to stop the state scheme. Finally, on 8 December, the federal cabinet decided not to interfere.

Professor John Mulvaney of Australian National University resigned from the council of the Museum of Australia in protest at the decision, arguing that the threatened area qualified for the heritage list under the United Nations convention's criteria for both cultural and natural properties — as well as having archaeological value the area contains an important natural habitat for huon pine trees, some as much as 2,000 years old.

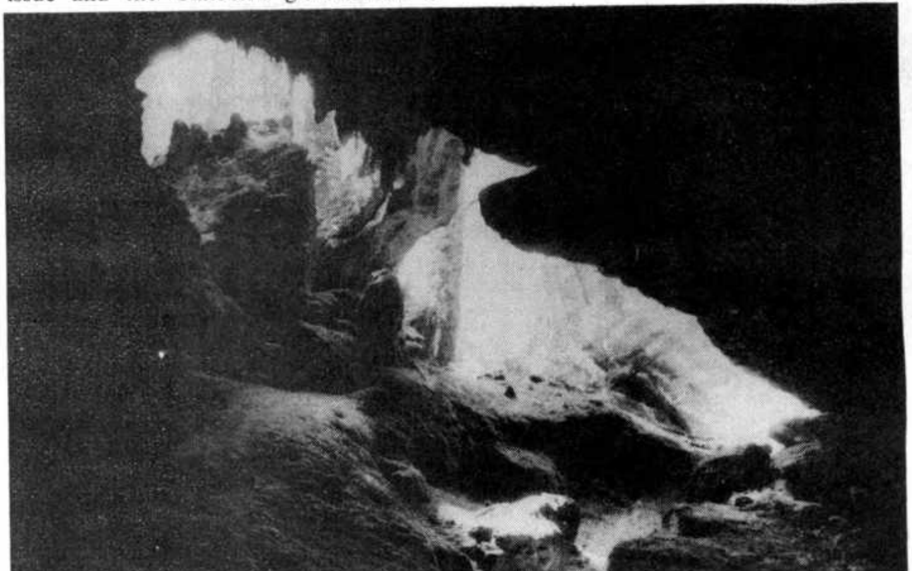
The relationship between national and state governments in Australia is a sensitive issue and the Canberra government is reluctant to oppose decisions made at state level. In this case the hydro-electric scheme is seen as a way of attracting industry to an area with the highest unemployment rate in Australia — 12 per cent — so it would be a major step for politicians to oppose it.

The farthest the government has so far gone in defence of the national park is a statement from Mr Thomas McVeigh, minister for home affairs and conservation, to the House of Representatives, saying the government "intends to enter discussions with the Tasmanian government with a view to minimizing the damage that the dam might cause . . . it will look towards an agreed management plan for the total area".



The argument that seems to have clinched the decision at last week's Paris meeting is that placing the national park on the heritage list will increase its chances of being preserved. Even so, the Tasmanian government is claiming that the listing gives the dam "the green light to go ahead" — a deliberate misinterpretation it seems.

Vimala Sarma



The entrance to Fraser Cave — due to be submerged if Tasmania's dam scheme goes ahead. In January last year stone tools and human remains dating from the last ice age were found here. The findings are reported in detail in the next issue of *Nature* (6 January 1983, p.28).

CORRESPONDENCE

Pole imprisoned

An open letter to the President of the Polish Academy of Science

Paris, 24 November 1982

SIR — We would like to raise the question of the fate of one of our Polish colleagues, Antoni Stawikowski, a matter which is of great concern to us.

Antoni Stawikowski is a research scientist at the Nicolas Copernicus Centre for Astronomy at Torun. He occupies an important position in the Polish astronomical community, having recently been appointed vice-president of the Polish Astronomy Society. Following his election in 1981 to the position of regional manager of the independent trade union Solidarity he asked for his responsibilities at the research institute to be temporarily suspended so that he could devote his attentions to his union duties.

He was interned on the night of 12/13 December 1981 following the declaration of a state of war in Poland. After a period of detention at Potulice prison he was transferred to the Strzebielinek internment camp. He was freed in August 1982 and returned to his research at the Nicolas Copernicus Centre for Astronomy at Torun.

Now, we have just learned that he appears to have been imprisoned again. We would be very grateful if you would outline the exact motives behind this new imprisonment and specify precisely the nature of the proceedings being brought against our colleague Antoni Stawikowski. We would also like to know his conditions of internment.

Whilst waiting for what we hope will be your rapid reply, we would like you to accept, Mr President, our respectful good wishes.

E. SCHATZMAN
(President)

On behalf of the Council of the Société Française des Spécialistes d'Astronomie, Paris, France

Chinese conundrum

SIR — M.C. McKenna incorrectly implies (*Nature* 18 November, p.212) that, in transcribed Chinese, disyllabic names are all given names and monosyllabic ones surnames. The reverse is true in the name provided for me by Chinese friends: Situ Li. Note also that in *pinyin* romanization there is no hyphen in disyllabic names. Incidentally Chinese names are not the only ones to give problems: a German correspondent once addressed me as "Herr Professor Doktor St. Philip".

PHILIP J. STEWART

Commonwealth Forestry Institute, Oxford, UK

Napoleon's health

SIR — In *Nature* of 14 October there were two contributions that bear relevance upon my own theory of criminal poisoning of Napoleon at St Helena. Lewin *et al.*[1] found no arsenic in a lock of hair obtained by Captain Poppleton, one of the British officers at St Helena. The sample did contain a moderately increased level of antimony, however.

Napoleon's health improved considerably during the first 9 months of his captivity. The length of hair that grew on Napoleon's head during this period can be estimated at 9-10 cm. The lock of hair obtained by Poppleton may well have been from this period.

It is more difficult to explain why the analyses showed an increased level of antimony. It is true that antimony is a component of tartar emetic, which was used as a medication, but it is also known that Napoleon stubbornly refused to accept medicines. As far as we know, Napoleon had no symptoms of antimony poisoning before March 1820. If the results of the analyses are correct, one is forced to question the authenticity of the sample.

One statement by Lewin *et al.* needs correcting. My theory of arsenic poisoning[2-4] was not based mainly on the high contents of arsenic found in hairs from Napoleon, but mainly on written evidence (diaries, letters, postmortem reports). The results of analyses of hairs must be seen as a confirmation.

Jones and Ledingham[5] found arsenic in wallpaper from the drawing room of Longwood. The authors mention that mould on damp wallpaper can metabolize arsenic compounds to volatile arsenic trimethyl. Leaving aside the question of how damp Napoleon's wallpaper was, the fact remains that the clinical picture is not one of continuous low-level poisoning. Napoleon repeatedly suffered from very severe attacks of illness; these were separated by periods of recovery. Analyses of hairs confirm that Napoleon repeatedly consumed relatively large amounts of arsenic.

For about 15 months, from July 1819 to September 1820, Napoleon enjoyed a relatively good health. During this period he could again go for walks, take part in gardening, and go horse riding. Napoleon's disease proceeded independently of any constantly active cause.

Furthermore, Napoleon did not live alone in his house. He was surrounded by an impressive staff of Frenchmen. The diaries do not report any symptoms of chronic arsenic poisoning among these. All this indicates that the wallpaper was not a major source of arsenic in Napoleon's case.

It is a common misunderstanding that Napoleon was killed by arsenic poisoning. The cause of his death was a combination of a liquid refreshment containing bitter almonds and a large dose of calomel given 48 hours before his death. Napoleon soon fell into deep unconsciousness (the effect of mercuric cyanide). The internal surfaces of his stomach became corroded (the effect of corrosive sublimate). The main purpose of the slow arsenic poisoning was to give observers the impression that Napoleon had some chronic disease, thus making his death appear more natural. Further details about the death-blow can be found in ref. 3.

Napoleon's arsenic

SIR — I wish to make the following comments on the article by Lewin *et al.* in *Nature* of 14 October (**299**, 627-628; 1982) which reported very much lower levels of arsenic in Napoleon's hair than we found (*Nature* **194**, 725; 1962).

The separation we used was a radiochemical one and the interference referred to by the authors as a possible explanation of our detection of high levels of arsenic is below the 1 per cent level. This is easily demonstrated by using the method.

Gamma-spectrometry as used by Lewin *et al.* is a poor method for arsenic analysis. Though for other investigations we use similar equipment (now standard) to that mentioned by the authors we still use the radiochemical separation for trace analysis. We have applied the technique to the analysis of several thousand of standards and samples since the investigation of Napoleon's hair.

Reprinting history

SIR — Reprints (also known as extracts, offprints) of articles from scientific journals have been used as a form of scientific information exchange for over two hundred years. Scientists have, since the early nineteenth century, acquired and collected them for their personal professional libraries. One well-known reprint collection is that of Wolfgang Ernst Pauli at the European Organization for Nuclear Research, Geneva (a list of it was published in 1969).

In connection with a study of the history of the reprint, I would appreciate hearing from scientists about the earliest reprints they have seen, what nineteenth century collections they may know of which may have survived, and the importance they attach to such collections.

ELLEN B. WELLS

Oncogene activation

SIR — The article by Reddy *et al.* (*Nature* **300**, 149; 1982) describes a relatively minor change in DNA structure which results in the activation of the T24 human bladder cancer oncogene. The change is a point mutation which according to the authors is a "mutation of guanosine into thymidine". Obviously, the intent of the authors was to describe a deoxyguanosine to thymidine transition, or better yet a mutation of guanine into thymine. Their error may seem trivial and perhaps amusing, were it not for the fact that such minor differences can have apparently significant consequences on the properties of genes, as shown by the work described in the paper. It is disconcerting that such a fundamental mistake was published in such an important article.

NEWS AND VIEWS

Disputes about the Earth's interior

Sir Harold Jeffreys and Dr R. A. Lyttleton are again at loggerheads. Both are mistaken to pretend that plate tectonics does not exist. Lyttleton is right to give another airing to Ramsey's theory.

The most conspicuous of those who reject the theory of plate tectonics is Sir Harold Jeffreys, now 91, who founded the school of geophysics at the University of Cambridge and who, with successive editions of his monumental book *The Earth* (the sixth was published in 1976), has spread his influence far and wide. Jeffreys is not so much an iconoclast as the opposite; far from being prepared to break the icons of the past, he would keep them bright and shining, as can be gathered from his insistence that the successive periods of mountain-building recognized by classical geologists must be explained by a shortening of the Earth's crust in turn caused by the contraction of the body of the Earth in the past 4,500 million years.

As it happens, Cambridge is also the base (some would say refuge) for another distinguished supporter of that view, Dr R.A. Lyttleton, who may nevertheless be better known for his contributions to celestial dynamics and to the theory of comets. So has Cambridge (where Vine and Matthews first demonstrated that the sea floor really spreads (see *Nature* **199**, 947; 1963)) become a place in which ideologically motivated men conspire to undermine the theory of plate tectonics? Not a bit of it. Far from making common cause, Lyttleton and Jeffreys have become persistent critics of each other's work. Their discontents, with plate tectonics but also with each other, are nicely illustrated by their latest contributions to the scientific literature.

First, Jeffreys. This month's issue of the *Geophysical Journal of the Royal Astronomical Society* (**71**, 555-566; 1982) includes Jeffreys's article "Tidal friction; the core; mountain and continent formation" in which he concedes an important point that Lyttleton has been urging on him for the past five years — that in attempting to relate the observed deceleration of the Earth's rotation to the influence of tidal forces, it is essential to allow for the possibility that the moment of inertia of the Earth may be changing. This important issue has its origins in Newton's theory of the motion of the Moon and in Halley's observation, in 1695, that compared with the predictions of that first serious essay in celestial mechanics, the Moon appeared to be decelerating in its orbit about the Earth. By the mid-nineteenth century, the reality of the deceleration (and that of the Sun and planets) had been firmly established and ascribed to the consequences of tidal friction. There are two effects — the Earth's rotational velocity is decreased, but (because angular momentum is conserved) the Moon retreats from the Earth (by about 3.5 cm a year) into an orbit in which the proper motion is decreased.

As it turned out, the first accurate estimates of the quantities concerned appeared only in the 1930s, when Spencer Jones (then the Astronomer Royal of England) was able to distinguish the secular deceleration of the Moon from the apparently random fluctuations of the Earth's rotational speed — a task then complicated by the use of the Earth's rotation as the standard of time. He estimated the secular acceleration of the Moon as -22.4 4.0 seconds of arc per century per century, well within a standard deviation of the values more recently obtained by laser ranging, from the longitudes on the surface of the Earth at which ancient eclipses were observed and by combining accumulated accurate observations of the planets. Jeffreys (like others) prefers a larger value, agrees with Lyttleton that the data do reveal changes of the moment of inertia of the Earth but considers that these may amount to a few parts in 100 million over the course of a decade. The explanation of recent fluctuations, Jeffreys says, is to be found in climatic change and the consequent redistribution of ice and water over the surface of the Earth. But attempts to pin down the long-term non-tidal contribution to the acceleration of the Earth's rotation should wait on more accurate observations even though the crustal shortening of at least 200 km needed on Jeffreys's view to account for mountain-building must have gone some way to offset the deceleration caused by tidal forces.

Lyttleton has no such inhibitions. His latest book, *The Earth and its Mountains* (Wiley, 1982), published in November, is a splendid *tour de force* intended to bring together his own interpretation of the secular acceleration of the Moon with a theory of the Earth's interior first put forward thirty years ago by the late W.H. Ramsey. As a contribution to the literature, Lyttleton's book has the virtue of being neither a didactic work nor an exercise in popularization but an argument addressed to people in all disciplines able to stomach some elementary algebra. On the basis of the ancient eclipse data, he concludes that the intrinsic acceleration of the Earth's angular velocity due to its decreasing moment of inertia is between a fifth and a quarter of the deceleration expected from the tidal forces of the Sun and Moon. (Lyttleton acknowledges R.H. Dicke's estimate in 1966 of an intrinsic acceleration only a little less.)

Lyttleton bravely and persuasively puts his faith in Ramsey's theory — the view that the molten core of the Earth differs from the mantle above it not in chemical composition but because of a phase transition from solid insulating rock to material of essentially the same composition in a liquid and electrically conducting phase. The theory originally advanced as a means of accounting for the average densities of the terrestrial planets (the Moon included) has the great advantage of consistency and simplicity. One of its particular virtues was to avoid the implausible assumption, current in the 1940s and 1950s, that the molten core consists solely of an alloy of iron and nickel. Shockingly, the papers presented at the Royal Society on the Earth's core in January this year include not a single reference to Ramsey's work (see *Phil. Trans. R. Soc.* **306**, 1-289; 1982) even though most recent attempts to account for the composition of the core involve attempts to "lighten" it with the admixture of elements such as oxygen, sulphur and silicon. The chief objection, that shock-wave and high pressure measurements with materials such as olivine have failed to demonstrate the required phase transition, may be irrelevant. Lyttleton is entirely right to carry a torch for Ramsey's theory, which is in that category of theories too neat not to be true. Needless to say, the steady growth of the Ramsey–Lyttleton core neatly accounts for the observed decrease of the Earth's moment of inertia, the contraction of the Earth's diameter in past aeons and thus for mountain-building.

Where does plate tectonics fit in? Lyttleton does not mention this other way of building mountains. Jeffreys refers with regret to the defection of Sir Arthur Holmes to "Wegener's theory" and says that attempts to account for the subduction of oceanic plates must be likened to "cutting butter with a knife also made of butter". Time will probably show that all the participants in this many-cornered quarrel are correct, or partially so. Lyttleton has scored an important point off Jeffreys, but Jeffreys is probably right to insist that the uncertainties about the motion of the Moon and composition of the Earth's core are still too great for a simple resolution of this long-standing dispute. Both of them should also admit, however, that the case for plate tectonics is too strong to be ignored, and both should admit that Ramsey's theory could yet turn out to be more interesting than they acknowledge. In its original version, the theory supposed that the solid rock of the mantle and the molten material of the core were identical in composition. But every chemist knows that multi-component systems in equilibrium with each other may differ in composition.

Onco Gen

from Peter Newmark

A pair of papers in this issue implicate two human genes, both of which have some pretensions to be called oncogenes, in the causation of specific cancers that are associated with chromosomal rearrangements.

The more advanced study is that of de Klein and his colleagues on page 765. They show that c-*abl*, the human gene homologous to the oncogene of Abelson murine leukaemia virus, is translocated from chromosome 9 to chromosome 22 in the leukocytes of three individuals with chronic myelocytic leukaemia (CML). The implication is that c-*abl* is activated as a result of its translocation and that the activation is associated with the disease.

The translocation between chromosomes 9 and 22 is found in over 90 per cent of cases of CML. One result is the so-called Philadelphia chromosome — chromosome 22 without its long arm. Another is the addition to chromosome 9 of the deleted section of chromosome 22. It has also been generally assumed that there is a reverse transfer of material. De Klein and colleagues prove that point by establishing that c-*abl* has shifted from chromosome 9 to the Philadelphia chromosome of CML leukocytes.

Highly suggestive, though this is, of an association between the c-*abl* translocation and the disease, it is only a beginning. Evidence will be needed that c-*abl* is activated by its shift to chromosome 22 perhaps by coming within the active domain of the immunoglobulin λ light-chain genes on that chromosome; and there is the unproven assumption that activation can lead to transformation. The viral gene certainly seems involved in transformation. It produces a tyrosine-specific kinase in Abelson murine leukaemia virus-induced lymphoid neoplasms of mice (although an unrelated transforming gene from such neoplasms transforms NIH3T3 cells in the standard assay for oncogenes — see *Nature* **300**, 659) but there is no evidence yet for a similar product in CML leukocytes.

Note also that c-*sis*, the human homologue of another viral transforming gene — that of the simian sarcoma virus — is shifted the other way in CML: from chromosome 22 to chromosome 9.

An even more tentative link between a human homologue of a viral transforming gene and a tumour with an associated cytogenetic abnormality is reported on page 773. The virus is Harvey murine sarcoma virus; the human gene has already been implicated in human bladder carcinoma (see p.762). McBride *et al.* now assign the normal allele of the gene (c-*bas*) to human chromosome 11 and point out that it is deleted in Wilm's tumour.

Caged ATP set free in muscle

from Peter D. Chantler

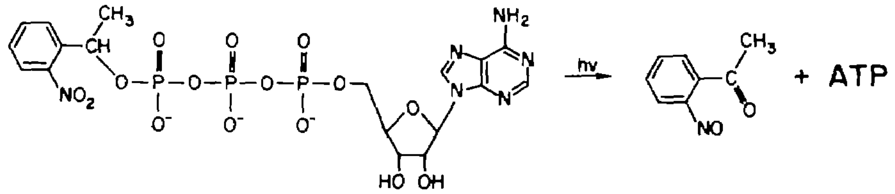
THE most noble aim of the biochemist, often discussed when inebriate, seldom when sober, is to relate the *in vitro* to the *in vivo*. This is never more true than in the field of muscle contraction where ordered arrays of aligned fibrils and interdigitating filaments have bolstered confidence that this elusive goal could be just around the corner, achievable by a plethora of physical techniques. And X-ray diffraction has come remarkably close. The recent time-resolved studies on isometrically contracting muscle[1,2] clearly indicate the power of this technique; evidence for a change in crossbridge orientation has been obtained on a millisecond time scale. Despite such advances, the democratic world of atomic masses will inevitably obfuscate a complete correlation of the *in vitro* with the *in vivo*. Other techniques are needed. One approach, due to Goldman, Hibberd, McCray and Trentham (see this issue of *Nature*, p.701), makes use of a novel molecule — caged ATP.

Caged ATP was first introduced by Kaplan and co-workers in 1978 (see ref. 3) who used it to study the (Na$^+$ + K$^+$)-ATPase in resealed erythrocyte ghosts. It is a chemically inert form of ATP, being a nitrophenyl derivative conjugated as the γ-phosphate ester of ATP. Photolysis at the suitable wavelength cleaves the molecule so as to yield ATP and 2-nitrosoacetophenone (see the figure and refs 3,4). The use of a frequency-doubled ruby laser at a wavelength remote from most protein absorption bands (347 nm) demonstrated a linear relationship between the degree of photolysis and the energy output of the laser[4]. Thus it became possible to design an experiment in which a known amount of ATP could be generated in a muscle fibre simply by controlling the total concentration of caged ATP and the energy of the laser pulse. Furthermore, caged ATP does not itself act as either substrate or inhibitor for the (Na$^+$ + K$^+$)ATPase[3] or for actomyosin[4] — a vital attribute if one wishes to monitor events on a millisecond time scale.

The first experiments performed by Goldman and colleagues (see p.701) were designed to determine the rate of detachment of crossbridges in rabbit skeletal muscle fibres. Single skinned rigor fibres were immersed in a bathing solution (no calcium) containing caged ATP which diffused into the fibre; no change in rigor tension resulted. At zero time, a pulse of 347 nm laser light (30 ns) was applied to liberate a predetermined burst of ATP, resulting in relaxation of the muscle fibre. Both tension and muscle stiffness were monitored. By varying the ATP concentration, the second-order rate constant for detachment could be measured and was found to be 2×10^5 mol^{-1}s^{-1} at physiological ionic strength and neutral *p*H, identical to that obtained for actomyosin dissociation[5] (0.5 M KCl) and only a factor of five lower than that for acto-HMM[6] (0.05 M KCl). The agreement suggests that the detachment rate constant is not substantially altered by the structural constraints of the filament lattice.

The effect of an imposed change in length, one second before the laser flash and consequent ATP release, was also investigated. If the rest-length rigor fibre (no calcium) was stretched 30μm before ATP release, the initial tension (similar to the force of an isometric contraction) decayed rapidly on photolysis with a half time of less than 10 ms. Alternatively, if the rigor fibre (no calcium) was released by 30μm before the laser pulse, the lower initial tension either remained constant or even increased before the final relaxation. The final phase of all relaxation transients superimpose. The rise in tension, following ATP generation after a short release step, is not an artefact of the system. Goldman and co-workers present a convincing argument that this effect is a physiological consequence of the type of thin-filament cooperativity first proposed by Bremel and Weber[7]. As noted above, detachment rates determined in the absence of calcium are fast; reattachment rates, determined by performing similar release experiments in the presence of calcium, are also fast and in agreement with X-ray results[2]. If, therefore, the laser-induced production of ATP in the fibre results in detachment of a large fraction of attached crossbridges and yet still leaves a proportion of rigor bonds (myosin heads without bound nucleotide), then even in the absence of calcium, force-generating crossbridges will re-attach because the rigor bonds push tropomyosin

Peter D. Chantler is in the Department of Biology, Brandeis University, Waltham, Massachusetts 02254.



Cleavage of caged ATP by light.

away from its blocking position[7]. The result will be a transient increase in tension before relaxation. Measurements of stiffness indicate a gradual decline in the total number of attached crossbridges throughout these events, indicating net detachment. As a *pièce de résistance* Goldman and collaborators model these release experiments using a three-step cycle involving active, rigor and detached bridges. Model and experiment are in good agreement.

Another approach of particular note, due to Thomas and co-workers, also relates the *in vitro* situation to the *in vivo* one using electron paramagnetic resonance (EPR) spectroscopy[8-11]. Spin labels, selectively and rigidly attached to myosin heads in glycerinated rabbit psoas fibres, have allowed the acquisition of data concerning head orientation[10] and submillisecond motion[9] during rigor and relaxation. The latest paper in this series (Cooke, Crowder and Thomas, this issue of *Nature* p.776) examines the orientation of spin-labelled heads during an isometric contraction. Labelled rigor muscle fibres show a distinctive EPR spectrum indicative of a highly oriented population of heads; a very different spectrum is obtained from the same fibres during relaxation, indicative of isotopic orientation[10]. When Cooke and colleagues add calcium to relaxed fibres causing an isometric contraction, the resulting EPR spectrum can be broken down into a summation of spectra from relaxed and rigor muscle fibres in the ratio of 4:1. No other orientations are seen; controls were performed to ensure that all heads were saturated with nucleotide.

Now, the paper of Goldman *et al.* (p.701) puts an upper limit of one per cent on the proportion of time a crossbridge spends as a true rigor bond during an isometric contraction. Hence the observation of 20 per cent spin-labelled heads having a highly ordered rigor-like EPR spectrum during an isometric contraction (Cooke *et al.* p.776) leads one to an ineluctable conclusion: the domain probed by the spin label on the myosin head does not change its orientation during the powerstroke. This conclusion is consistent with the observation that an applied stress imposed on rigor muscle fibres also does not alter the orientation of the domain probed by the spin label[11]. Nevertheless, although part of the myosin head may well be immobile during the power stroke, the demonstration of work production by actomyosin machines using only soluble proteolytic subfragments of myosin (myosin heads)[12] restricts the conformational changes necessary for force generation to other domains on the head itself, rather than the myosin tail. □

Transcellular cross-talk between epithelial cell membranes

from Jared M. Diamond

OUR bodies are catacombs of spaces connected to the outside world and filled with fluid. The spaces include the lumina of the intestine, kidney tubules, and salivary and sweat ducts. Separating these spaces from the bloodstream are cell sheets called epithelia, which secrete or absorb fluids by pumping ions from the blood into the spaces or vice versa. An enormous boost to epithelial research came when the Danish physiologists Ussing and Zerahn[1] devised a new method of measuring the pumping of ions in 1951. Seven years later Koefoed-Johnsen and Ussing provided a second leap forward with a new model to explain the pumping[2]. The model has evolved considerably in subsequent years, and this evolution is in turn relevant to the theories of scientific models proposed by historians of science. Several papers published in recent months report further significant advances[3-5].

The Koefoed-Johnsen and Ussing (KJU) model sought to explain sodium absorption, a dominant transport mechanism in many epithelia. In the 1950s, students of nerve, muscle and erythrocytes had discovered how these cells regulate intracellular cation content through three membrane processes: passive permeation of Na^+, passive permeation of K^+, and active ATP-driven extrusion of Na^+ coupled to uptake of K^+. The KJU model was couched in terms of these same three processes and postulated their restriction to one or other face of the sheet: passive Na^+ entry to the cell membrane facing the lumen, and passive K^+ exit and active Na^+-K^+ exchange to the cell membrane facing the blood (Fig.1*a*). Part of the model's appeal was that it postulated no new processes beyond those already known to regulate ion movement between cell interiors and the blood. The limitations of these postulates were also the major focus of the model's further evolution.

Epithelia are not merely polarized cells arranged in a sheet. Each cell in the sheet is joined to its neighbours by junctions, which in principle offer a path across the epithelium that by-passes the cells. The KJU model, and epithelial research of the 1950s generally, ignored the possible importance of this path. In the late 1960s and early 1970s, when new techniques became available, it turned out that the alternative route was not, indeed, important for one class of epithelia, now termed tight epithelia. In such tissues, exemplified by frog skin, mammalian and amphibian urinary bladders, and stomach, ions cannot pass through the junctions and must traverse the epithelium via the cells. However, in 'leaky' epithelia, exemplified by renal proximal tubule, small intestine and gallbladder, the junctions are the major route for passive transepithelial movement of ions. Tight and leaky epithelia have subsequently been found to differ in the way in which Na^+ enters the epithelial cells across the lumen-facing (apical) membrane. In tight epithelia, as well as in the medium-tight large intestine and renal distal tubule, Na^+ enters by a highly specific mechanism that is inhibited by very low concentrations of amiloride and that recent measurements of electrical noise have shown to be an ion channel[5,9]. In contrast, in leaky epithelia Na^+ entry is coupled to the entry of a partner (a non-electrolyte such as sugar or amino acid, or Cl^-), or perhaps to H^+ exit in parallel with Cl^-/HCO_3^- exchange. This process is believed, but not firmly proved, to involve a carrier[10,11].

A recent modification of the model came from the discovery that the pump at the blood-facing (basolateral) membrane does not swap 1 Na^+ for 1 K^+, as originally assumed, but rather 3 Na^+ for 2 K^+, as is also true for nonepithelial cells[5,12-14]. More major changes have, however, focused on how ion movements at the apical and basolateral membranes regulate each other[15]. Apical Na^+ entry is greatly stimulated by physiological agents such as luminal nutrients, aldosterone and antidiuretic hormone. What prevents the rate of apical Na^+ entry from exceeding that of Na^+ extrusion by the basolateral pump, leading to osmotic lysis? Increased basolateral Na^+ extrusion is coupled to basolateral K^+ uptake: how is the cell similarly protected against osmotic lysis through increased K^+ content? Other physiological agents, such as CO_2 and insulin, stimulate basolateral Na^+ extrusion: what then signals the apical membrane to become more permeable to Na^+, lest apical Na^+ entry become rate-limiting? Do conditions that stimulate

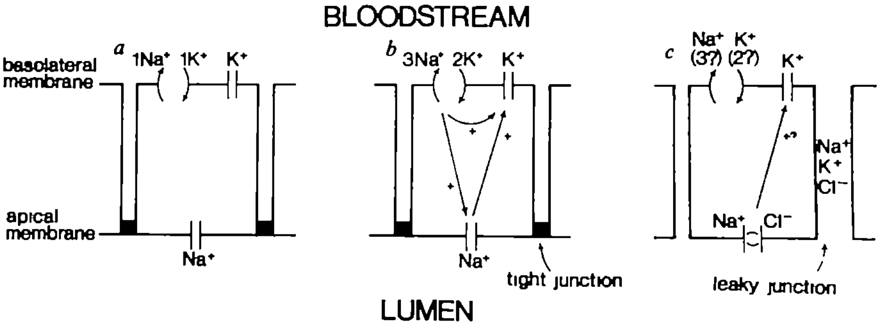
apical Na$^+$ entry then stimulate basolateral Na$^+$ extrusion through a rise in cell Na$^+$, or is there a different signal? In retrospect, our understanding of epithelial transport in 1958 resembled an economic study of the banking system that considered savings inflow and loan outflow, without having begun to ask how inflow and outflow regulated each other by determining savings and loan interest rates.

The first indication of cross-talk between apical and basolateral membranes came in 1961, when MacRobbie and Ussing[16] used cell swelling as an indirect measure of ion entry in frog skin. They found that inhibiting the basolateral pump reduces the ionic permeability of both the basolateral and apical membranes. The effect on apical Na$^+$ permeability has now been documented more directly in numerous tight epithelia by electrical methods[17-19]. (It has yet to be demonstrated for a leaky epithelium.) Stimulating the pump with CO_2 increases apical Na$^+$ permeability, while inhibiting the pump by metabolic poisons or by the specific pump inhibitor ouabain reduces apical Na$^+$ permeability. The effect makes sense teleologically: shutdown of basolateral Na$^+$ exit leads to shutdown of apical Na$^+$ entry, protecting the cell against osmotic lysis. But this result, however desirable, is paradoxical. The simplest expectation from shutdown of basolateral Na$^+$ exit would be a rise in cell Na$^+$, tending to increase apical Na$^+$ conductance because of the higher concentration of the conducting ions. In fact, apical Na$^+$ conductance decreases.



Evolution of the Koefoed-Johnsen and Ussing model of epithelial transport. *a*, As originally postulated in 1958. *b* and *c*, The present form of the model applied to tight (*b*) and leaky (*c*) epithelia.

The converse type of cross-talk, a regulation of the basolateral membrane by the apical membrane, has just been demonstrated by two recent papers. In the tight epithelia toad and frog urinary bladders, Davis and Finn[3] showed that blocking the apical Na$^+$ channel with amiloride decreases basolateral K$^+$ conductance as rapidly as apical Na$^+$ conductance. In the leaky epithelium Necturus small intestine, Gunter-Smith, Grasset and Schultz[4] found that addition of the sodium ion's transport partners, alanine or glucose, to the luminal bathing solution rapidly increases apical conductance, then more slowly increases basolateral conductance. Furthermore, there is now extensive evidence of feedback within the basolateral membrane: an increase in activity of the basolateral Na$^+$–K$^+$ pump goes hand-in-hand with an increase in basolateral K$^+$ conductance[4,15,19,20]. What remains unclear is whether this basolateral K$^+$ conductance is part of the pump itself, or whether it arises from a separate channel. It is also uncertain whether a rise in cell Na$^+$ is the principal means by which increased apical conductance leads to increased basolateral pumping, since searches for the expected rise in cell Na$^+$ have yielded conflicting results[21-23].

What signalling agent is involved in these feedback circuits? The leading contender is changes in intracellular Ca^{2+}, normally maintained at a low concentration by countertransport of Na$^+$ versus Ca^{2+} at the basolateral membrane[24-26]. In other words, Na$^+$ entry downhill into the cell at the basolateral membrane drives the uphill extrusion of Ca^{2+}, so that reduction of the Na$^+$ downhill gradient through a rise in cell Na$^+$ would lead to a rise in cell Ca^{2+}. To explain the observed feedbacks, one would also have to assume that raised cell Ca^{2+} increases basolateral K$^+$ conductance but decreases apical Na$^+$ conductance. It remains to be determined whether physiological changes in cell Ca^{2+} caused by changes in cell Na$^+$ do produce these conductance changes.

All these examples of transcellular cross-talk have involved Na$^+$ transport. A possible example for another ion has emerged from studies by Machen and colleagues[27-29] in gastric mucosa, where increased Cl$^-$ transport is associated with increased transepithelial conductance. The effect appears to involve increases in basolateral K$^+$ conductance and in apical Cl$^-$ conductance.

Similar interactions between conductances may also appear in isolated cells, as exemplified by an effect of Na$^+$ entry on K$^+$ conductance in hepatocytes[30]. However, it is proving harder to discover feedback links in isolated cells, where the interacting conductances coexist in the same membrane, than in epithelia, where they are conveniently segregated in opposite membranes.

Comparison of Fig. 1*a* with Fig. 1*b* and 1*c* makes clear that the KJU model has evolved considerably since it was proposed in 1958. In tight epithelia (Fig. 1*b*), the pump is now believed to be electrogenic instead of neutral, and three feedback mechanisms have been added. In leaky epithelia (Fig. 1*c*) a major parallel pathway and one feedback mechanism have been recognized, and the apical entry step is now considered not to be of Na$^+$ alone. These developments illustrate why, in the past two decades, philosophers of science have talked less about the verification or falsification of models, and more about the evolution of models within a continuous framework (for example, the paradigm or disciplinary matrix of Kuhn, the research programme of Lakatos)[31].

But the history of the KJU model also illustrates that, even at a given stage, a model's acceptance does not depend solely on its verifiability, or on its success in surviving attempts at falsification. Through much of the 1960s and the early 1970s many experimental findings argued against even the basic premises of the KJU model[32-38]. Why did the model nevertheless remain widely accepted through this period? The fact that today's evidence happens to support the model does not resolve the dilemma, for this outcome was not foreseen from yesterday's evidence.

Several factors may have contributed to this paradox. Although the KJU model conflicted with some important findings, there was never a serious alternative that could begin to resolve these conflicts while matching the successes. Although there

were doubts about the correctness of the KJU model, its use continued to suggest numerous experiments that yielded significant results. There was concern that the error was not in the model but in the contrary findings: for instance, in estimates of intracellular ion concentrations by indirect chemical means, superceded recently by direct measurements through ion-specific microelectrodes.

Finally, the model was beautiful, simple and reductionist: it made epithelial phenomena emerge from established properties of isolated cells. In contrast, the findings conflicting with the model were complex, intellectually unappealing and unconnected to work on isolated cells. Given a choice between what seemed to be a beautiful model and ugly findings, physiologists preferred the model. Now, many of the ugly findings that conflicted with the model can be explained by our newly-gained understanding of cross-talk. Beauty and truth are once more united! □

Trypanosoma cruzi: signals for transformation

from F.E.G. Cox

Trypanosoma cruzi is the causative organism of Chagas' disease, a disease that affects between 12 and 24 million people in South and Central America and causes considerable mortality and morbidity. The trypanosome is transmitted by numerous species of blood-sucking reduviid bugs. Trypanosomes in the trypomastigote form are taken up by the bug when it feeds and transform into epimastigote forms in the anterior part of the insect's gut. They then multiply by binary fission, building up vast numbers. Transmission becomes possible when the epimastigotes transform back into trypomastigotes again and pass into the hindgut where they are voided with the faeces to enter the victim through abrasions in the skin. The bugs live for long periods and, having become infected, remain infective for life, so providing a continuous threat to all those who might subsequently be bitten.

The signals that trigger these transformations have not yet been definitely identified but it seems certain that the membrane surface of the epimastigote form recognizes signals provided by the intrinsic or extrinsic contents of the insect's gut. The membrane surface is very complex and contains polysaccharides, lipopolysaccharides and glycoproteins. The carbohydrate components can be identified using lectins[1], and peanut butter agglutinin can be used to extract galactose-terminal glycoproteins[2]. Monoclonal antibodies can also be used to identify glycoproteins[3]. The tools with which to study the signals responsible for transformation in the bug are therefore available.

It has been suggested that the lectins already identified in the insect gut might regulate the morphogenesis of the trypanosome[4]. One of the molecules possibly involved has now been identified[5] in a letter that has just appeared in *Nature* (Sher, A. & Snary, D. **300**, 639; 1982). Epimastigotes do not readily transform into trypomastigotes (a problem that has also troubled workers using African trypanosomes) and Sher and Snary[5] devised a technique whereby epimastigotes enclosed within Millipore chambers were transplanted subcutaneously into mice, left in position for 7 h, withdrawn and transferred to an appropriate culture medium. In these conditions, epimastigotes transform into trypomastigotes, a change that does not occur if the *in vivo* 'programming' is not carried out. Using this technique, Sher and Snary were able to investigate the inhibitory effects of six monoclonal antibodies against epimastigote surface components and one lectin, wheat germ agglutinin. The substances to be tested were introduced into the culture media containing 'programmed' epimastigotes and the proportion transformed calculated.

The experiments showed that only one of the monoclonal antibodies inhibited transformation from the epimastigote to the trypomastigote form. The antibody had already been shown to be directed against a cell-surface glycoprotein with a molecular weight of 72,000 (ref.3). It does not affect the longevity or motility of the epimastigote, only its ability to transform into a trypomastigote. The lectin had no inhibitory effect. The results suggest that in the midgut of reduviid bugs there exists a substance, or substances, which reacts with the 72,000-molecular weight glycoprotein on the epimastigote surface and inhibits transformation into the trypomastigote form. Whether or not this is one of the lectins previously described has yet to be determined.

The significance of these findings is that they provide a clue as to why epimastigotes are inhibited from transforming into trypomastigotes. The inhibition probably serves two purposes — to accumulate epimastigotes in the midgut until such time as a relatively large proportion can transform into trypomastigotes, so ensuring the infection of a new host; and to retain a number of untransformed epimastigotes for later transformation and infection. Parasites need to be retained in the midgut because the nutritional conditions are more favourable there than in the hindgut.

From an epidemiological point of view the findings are very interesting. Many bugs can transmit *T. cruzi* but not all do so equally well and it is possible that the potential to act as a reservoir of infection also varies. Susceptibility and the ability to transmit the infection may be tied up with the interactions between surface molecules and insect products and as there are quantitative and qualitative differences between the surface components of different strains of *T. cruzi*[6] it may well be that a full understanding of Chagas' disease will depend on developments at the molecular level. The findings may also be significant in other situations; in leishmaniasis, for example, lectins have also been shown to bind to the surfaces of the parasites and the capacity to bind to vary between species and strains[7]. Monoclonal antibodies, at present largely the tool of immunologists, may become equally important to epidemiologists. □

THE SONORAN HELODERM

(*Heloderma suspectum*)

At least one form of lizard is endowed with the faculty of producing a poisonous bite. The possessors of these formidable weapons of defence are the members of the genus *Heloderma* of naturalists, one species of which was long ago described from Mexico under the appropriate name *Heloderma horridum*. This lizard has not only grooved teeth, after the manner of many of the poisonous serpants, but likewise highly developed salivary glands, which issue at the bases of the teeth with the evident purpose of carrying poisonous saliva into the grooves.

From *Nature* **27**, 153; December 14, 1882.

Why is the stratosphere dry?

from Reginald E. Newell

MORE than 30 years ago Brewer and Dobson[1,2] suggested that the stratosphere is dry because air enters from the troposphere only in the vicinity of the cold tropical tropopause. They proposed that the tropical tropopause acts as a cold trap for moisture, limiting the stratospheric moisture to saturation mixing ratio values at the trap temperature. Working backwards from middle-latitude observations the required cold trap temperature is about −84°C. The general theory Brewer and Dobson still holds but the details of the actual troposphere-to-stratosphere transfer are not understood. Does the transfer occur by a steady rising motion or is it part of the active cumulonimbus convection occurring in the tropics? A series of papers[3-9] published in *Geophysical Research Letters* this year gives some insight into the processes involved.

Brewer and Dobson based their theory on frost-point measurements made from aircraft over England, which showed that whatever the conditions in the troposphere, the stratospheric water vapour mixing ratio dropped sharply just above the tropopause to values close to 2 μg of vapour per gramme of air, only one ten-thousandth of the value just above the tropical sea surface. Mastenbrook[10] subsequently adopted Brewer's frost-point hygrometer for balloon use and found similar low mixing ratios in the tropical stratosphere with a seasonal variation generally in phase with the cold trap temperature.

The recent papers in *Geophysical Research Letters* provide the first results from an exploration of the tropical tropopause region by the NASA high-flying U-2 aircraft which was based in Panama during September 1980. The aircraft was equipped with an array of modern instrumentation and made a series of flights to measure temperature, water vapour, aerosols, ice crystals and other atmospheric trace constituents. The results show a water vapour minimum at about 19 km, a few kilometres above the temperature minimum at the tropical tropopause, with mixing ratios down to about 2.2 μg g^{-1}, significantly lower than the saturation mixing ratios ($\sim$ 3.8 μg g^{-1}) at the observed tropopause temperatures (around −80°C). The air at 19 km had clearly not entered the stratosphere through the tropopause at Panama. The water vapour was measured with two instruments, a new Lyman-α photodissociation hygrometer[8] and a more conventional broad-band IR radiometer[9], and both showed the same general findings.

Aerosols with radii greater than 0.03 μm were collected by a wire impactor and examined in the laboratory with a scanning electron microscope[6]. It was found that the concentration of small particles diminished and that of larger particles increased with height above the tropopause. The small particles seem to be introduced into the stratosphere by convective activity, though where and when the injection occurs is not known; coagulation seems to be the main mechanism of loss.

The U-2 pilot was bold enough to penetrate the cirrus anvil on several occasions (a somewhat risky procedure as it is hard to see from above where there might be convective updrafts penetrating the lower part of the anvil) and a probe was used to record two-dimensional shadow images of ice crystals in the size range 40–2,500 μm (ref. 7). In addition, an active cavity laser spectrometer was used to measure the size distribution of aerosols in the 0.1–0.3 μm size range. Inside the anvil there was a particular abundance of aerosols having a radius of 0.17 μm which Knollenburg and co-workers think is due to new nucleation and growth of solution droplets[7]. This is just one item from the large amount of new data on anvil particles that was collected in Panama.

To accompany the aircraft measurements, enhanced IR photographs of the tropical clouds were produced from the Atlantic Geosynchronous Satellite[4]. These showed the time evolution of the convection and the large extent of the anvils, although there were only a few points where the equivalent temperature was lower than −82°C, in agreement with the aircraft observations.

It had been thought that the moisture in the rising air would condense out to form cirrus cloud and the ice crystals would be left in the troposphere[1,2]. Danielsen[5] has examined the new data with this view in mind and interprets it in terms of what he calles 'a dehydration engine'. He describes how a rising cumulonimbus cloud can overshoot the level of zero buoyancy and the anvil form from air that has descended after some mixing with warmer and drier air of the lower stratosphere. The anvil base extends far beyond the parent convective cloud, as shown by the satellite IR images, and is heated by the interception of upwelling IR radiation. The satellite images and aircraft data together suggest an IR emissivity close to unity for the anvil top and this region cools by radiation to space. Static instability is thus maintained in the anvil by radiation and there is a turbulent heat flux from the base to the top for balance. Because the anvil base is about 10°C warmer than the top and saturation vapour pressure increases with temperature, there is a vertical gradient of moisture and an upward moisture flux is produced by the turbulent transport. Near the top of the anvil there is supersaturation, perhaps even with respect to water according to the observations, and ice crystals grow and fall relative to the air, providing the water sink for the system. The engine mechanism yields a vertical temperature profile with two minima and an intermediate warmer region due to anvil subsidence; the two minima are observed in the flight data. Furthermore, calculations of IR cooling from the ice crystal data and from the IR radiometer data[7] show cooling rates near the top of the anvil of up to 15°C per day, giving further support to Danielsen's engine concept.

The finding that the water vapour mixing ratio is at a minimum near 19 km, well above the tropopause, and has values smaller than saturation values at the tropical tropopause suggests that air enters the stratosphere in a region where the tropopause is colder than that at Panama. Considerations of the world-wide distribution of temperature indicate that the tropical western Pacific is a region where the exchange might occur, particularly in the December–February season[5,8,11].

That possibility, and Danielsen's concept of a 'dehydration engine', could be tested by carrying out a similar experiment in that region, and with more extensive radiative measurements it should be possible to check Danielsen's predictions of a radiatively produced instability. Even in the western Pacific convection can only dehydrate the air just above the tropical tropopause. The dry air seen at 19 km at Panama must have risen by a gentle rising motion that would accompany radiative heating of the region above the convection and this process would take place while the air moves in a longitudinal direction.

That there is a minimum in the mixing ratio at all is perhaps surprising as the early ideas were that the mixing ratio should be constant with altitude above the tropopause. Indeed, an observation of increased mixing ratio at higher altitude was often explained as contamination[10]. But it is now

thought that significant quantities of water vapour may be formed at higher altitudes by chemical and photochemical reactions which destroy methane[12], another gas that passes into the stratosphere through the tropical tropopause. In fact the results of these experiments will have a general applicability to the transfer of all tropospheric trace gases into the stratosphere[13]. For most of these the transfer is not limited by a physical property, such as the variation of saturation vapour pressure with temperature that limits the stratospheric water content, and if fresh tropospheric air is sampled above the tropopause in a region such as the western Pacific it should be possible to detect relatively short-lived tropospheric species.

Bright future for liquid electrolyte solar cells?

from A. Hamnett and S. Dennison

THE past decade has seen major efforts to develop photoelectrochemical devices that directly convert light to electricity. The devices are based on the junction between a semiconductor and a liquid electrolyte, but problems of corrosion and efficiency have bedevilled their successful development into a technology that could rival the more familiar solid-state p–n junction solar cells, where efficiencies of more than 20 per cent have been attained. The superiority of the solid-state p–n device may, however, appear a little less assured with a report in this issue of *Nature* by C. Gronet and N. Lewis of Stanford University (see p.733) who describe a photoelectrochemical cell (PEC) based on n-GaAs$_{1-x}$P$_x$ in acetonitrile and using as redox couple the ferrocene-ferrocinium system. The cell has an operating efficiency of 13.2 per cent in natural sunlight, a figure considerably in excess of any previously reported from a non-aqueous cell.

The essential principles of the liquid-junction photovoltaic device can be understood with reference to the figure. If an n-type semiconductor is placed in a concentrated electrolyte and subjected to a positive bias, the region of the semiconductor near the surface becomes depleted of electrons. When light of sufficient energy is absorbed in this 'depletion layer', the electric field is able to separate the resultant photogenerated electron (in the upper or conduction band) from the positively charged vacancy or 'hole' left behind in the lower or valence band. The direction of the field is such as to drive the 'hole' to the surface, where it is transferred to the reduced form, R, of a suitable redox couple O/R. The electron, meanwhile, is transported around the external electrical circuit, performing work e_0V, finally reducing O at the metal counter-electrode. No net chemical change occurs in the cell, but light energy $h\nu$ is converted to electrical work e_0V. The figure makes it clear that there will be two limiting cases; the open-circuit voltage V_{oc}, which is the maximum voltage obtained at zero current, will be approximately the difference between the potential corresponding to the conduction band edge and the redox potential of O/R. By contrast, the maximum current is obtained when the two electrodes are short-circuited. Between these two extremes, there will be a current-potential region where useful work can be obtained; owing to the spectral distribution of the solar spectrum, there will also be an optimal bandgap for the semiconductor which is $\sim$ 1.4 eV, though bandgaps between 1.0 and 1.8 are likely to be effective.

Although the principles of this cell have been known for some years, it has proved extremely difficult to build practical devices based upon them. Four problems have arisen that have proved especially obdurate; of these, photocorrosion is the most serious and occurs when some of the photogenerated holes arriving at the surface become diverted from the desired reaction (conversion of R to O) and instead oxidize the surface of the semiconductor. To avoid this, a very fast rate constant for the oxidation of R is necessary, which minimizes the concentration of holes at the surface. A second related problem is that holes at the surface may also be diverted to electronic energy levels that are localized in the surface region — so-called 'surface states'. If these lie near the conduction band edge, they may in turn capture an electron from the conduction band, the net effect being the degradation of the light energy to heat. In aqueous solutions especially, surface states near the conduction band edge are very common and are thought to be due to protons. Much effort and ingenuity has gone into attempts to mitigate the deleterious effects of these states.

Closely related to this is the problem of grain-boundary recombination; ideally, the semiconductors used in such photovoltaic devices should be polycrystalline rather than single-crystal materials. From the economic standpoint, polycrystalline materials are enormously advantageous, but solid-state p–n junctions using them have proved extremely difficult to fabricate. This is because such junctions are made by taking a slice of n- or p-type material and diffusing into it, from the surface, impurity atoms that dope it locally in the opposite sense. Since diffusion down grain boundaries is far more rapid than diffusion in the bulk, it is prodigiously difficult to control the width of the junction in polycrystalline samples. No such fabrication problems arise in the liquid-junction photovoltaics described above, but recombination of carriers at the grain boundaries can cause a severe drop in operational efficiency.

The third problem is the kinetics of the O/R couple. We have seen that oxidation by holes must be rapid to compete with photocorrosion and surface-state capture processes, but additionally the kinetics of reduction of O to R must also be fast to reduce the overpotential at the metal cathode. In effect this means that the O/R couple must be highly electrochemically reversible.

Finally, strong chemisorption of the redox couple onto the electrode can occur. If both R and O strongly adsorb on the semiconductor surface, conversion of R to O will alter the charge balance at the interface. This in turn will reduce the electric field in the depletion layer, reducing the rate at which photogenerated holes can be

The design of the liquid-junction photovoltaic device. O/R is the redox couple.

0028-0836/82/510687-02$01.00

transported to the surface. A steady state is set up in which the change in the depletion layer charge is determined by the relative rates at which holes can be fed from O_{ads} to R in solution and the rate at which they can be supplied by the electrode. If the former rate is slow, the overall quantum efficiency will be very low.

In attempting to overcome these problems, a great deal of effort has been invested in pursuing a detailed understanding of the fundamental surface processes on semiconductors in contact with aqueous and non-aqueous electrolytes. In parallel with this work, novel methods of chemically modifying the surface to improve the quantum efficiency have been explored, and a large amount of phenomenological information gathered. Heller's group at Bell Laboratories has been especially active in this field, and has made considerable progress in reducing the effects of corrosion and surface-state recombination in cells based on aqueous electrolytes. The technological price has, however, been severe; water is a highly corrosive solvent, partly because of its excellent solvating properties, and complex measures for protecting the surface, involving various chemisorbed metal ions, have had to be developed.

These technological difficulties have had a rather discouraging effect on aqueous photovoltaic work. In an effort to avoid some of the problems, several groups around the world have begun programmes of research into non-aqueous electrolytes. Initially, behaviour was found which suggested that chemisorption of the redox couples used was very common, and it was suggested that these cells would therefore have an intrinsic limitation to their efficiencies. However, it now appears from the work of Gronet and Lewis, reported in this issue, that no such intrinsic limitations exist. By using n-type $GaAs_{1-x}P_x$ electrodes and extremely straightforward cell design, they have obtained efficiencies of over 13 per cent. This is a remarkable result especially as, by the authors' admission, the cell is quite unoptimized. There can be little doubt that this result will lead to a considerable reassessment of liquid-junction photovoltaic devices and the obviously urgent task is now to investigate the use of polycrystalline electrodes to see whether the real advantages of such cells can be realized. □

Keratinocyte culture club

from Fiona M. Watt

In recent years new techniques for the cultivation of epidermal cells (keratinocytes) have generated enormous interest among clinicians and biologists alike. Dermatologists are attracted by the possibility that keratinocytes from patients with skin disorders may behave abnormally *in vitro*. Given the clinical importance of squamous cell carcinomas, tumour biologists are discarding fibroblasts in favour of keratinocytes for many *in vitro* models of transformation and carcinogenesis. Keratinocytes appeal to the cell biologist too: as a system for studying terminal differentiation and population kinetics; for investigating basement membrane synthesis and the structure and function of keratin filaments. Scientists with these diverse interests gathered recently at a symposium on keratinocyte biology* which turned out to be lively and thought-provoking.

Methods of cultivating keratinocytes seem to proliferate more rapidly than the cells themselves, but generally fall into two categories: first, relatively simple systems for serial passage of cells, in which some of the properties of intact epidermis are retained; second, more elaborate attempts to reconstruct true epidermis in primary culture by approximating a normal epidermal environment. Of the first group, the most successful is undoubtedly that of Rheinwald and Green (*Cell* **6**, 331; 1975), in which human keratinocytes can be grown for many generations on a feeder layer of 3T3 cells. There have been several attempts to eliminate the requirement for feeder cells and a new chemically defined medium for human keratinocytes seems quite promising (S. Boyce, University of Colorado). It is harder to persuade mouse keratinocytes to proliferate *in vitro*, and consequently most cultures are seeded at high density. A low level of calcium ions (< 0.1 mM) enhances proliferation of newborn mouse epidermal cells (H. Hennings, NCI), but as this prevents stratification, normal terminal differentiation, in which a steady state is achieved between basal cell division, suprabasal differentiation and cell shedding, is not observed.

The histological appearance of cultured epidermis can be improved by growth on a 'dermal equivalent' — a collagen gel containing fibroblasts (E. Bell, MIT). Further attempts to mimic the normal environment of epidermal cells include culturing at an air-liquid interface, feeding cells from below and providing a growth substrate of basement membrane components, all of which can improve the differentiated morphology of primary cultures (M. Prunieras, Fondation Rothschild; I. Mackenzie, University of Iowa).

In order to analyse normal differentiation or to define abnormalities in disease, it is essential to have good biochemical markers of keratinocyte differentiation; morphological criteria are not enough. Late in terminal differentiation an intracellular envelope of protein cross-linked by transglutaminase is formed. So far, two envelope precursors have been identified and solemnly named — involucrin (R. Rice, Harvard University) and keratolinin (not to be confused with keratohyalin) (L. Peterson, Oregon Health Sciences University). While it is still too early to say how many envelope precursors there are and how they are related, individually they provide good markers of terminal differentiation. Lectin binding by keratinocytes changes during differentiation, reflecting altered membrane glycosylation (P. Elias, VA Medical Center, San Francisco; F. Watt, Kennedy Institute). Such changes in keratinocyte surface properties might influence cell recognition and adhesion and could account for the sorting out of differentiating cells during stratification. Monoclonal antibodies to keratins reveal patterns of keratin synthesis characteristic of different stages of differentiation (T.-T. Sun, New York University). With elegant new STEM and linear mass density studies on keratin filament structure (P. Steinert, NCI) and with amino acid sequences of individual keratins obtained by gene cloning (E. Fuchs, University of Chicago; D. Roop, NCI), the biological significance of keratin heterogeneity may at last become clear.

Certain skin disorders, such as congenital ichthyosis, are characterized by distinct ultrastructural abnormalities which may continue to be expressed *in vitro* (I. Anton-Lamprecht, Institute for Ultrastructure Research, Heidelberg). However, good morphological criteria of disease are unusual in keratinocyte cultures, and many studies of potential clinical relevance are hampered by failure to exploit the known biochemical markers of normal terminal differentiation instead. This will surely change before long: it is exciting to learn, for example, that human cervical displasia is correlated with a decrease in involucrin synthesis, as this should be amenable to analysis in culture (R. Rice). □

REVIEW ARTICLE

Changes in the solar constant and climatic effects

John A. Eddy, Ronald L. Gilliland & Douglas V. Hoyt

High Altitude Observatory, National Center for Atmospheric Research, PO Box 3000, Boulder, Colorado 80307, USA

Spacecraft measurements have established that the total radiative output of the Sun varies at the 0.1–0.3% level. The observed fluctuations are well modelled as radiative deficits proportional to the area of the solar disk covered by sunspots. Historical records of projected sunspot areas allow an accurate reconstruction of these short-term fluctuations over the past century. Such changes can be expected to perturb the terrestrial surface temperature by a fraction of a degree centigrade and probable evidence of this solar-induced signal has been found. The effect, though important in terms of understanding the climate system, is too small to be significant in practical weather or climate predictions.

RADIATION from the Sun is the dominant source of energy input to the Earth's atmosphere. Solar energy, coupled with the rotational inertia of the spinning planet, drive the circulation patterns of oceans and air that are the basis for all the phenomena known as weather and climate. Regional weather patterns may result from local perturbations of geographical, orographic, or other origins, including anthropogenic ones, but all of these processes depend on a fundamental flux of solar energy. The equilibrium temperature of the Earth's surface and seas is ultimately determined by a balance between solar radiation absorbed by the Earth, primarily at visible and near IR wavelengths, and long-wave radiation that is re-emitted to space. Should the total solar input vary as a persistent trend, the surface temperature of the Earth will in time respond in a direct and predictable fashion: global cooling in response to decreased solar radiation, and warming following an increase. The diurnal variation of cold nights and warmer days, and seasonal patterns from winter to summer attest to the role of insolation as the principal temperature control.

Such reasoning has prompted innumerable attempts at identifying the signature of solar variability in climate records. What is surprising is how difficult it has been to find any unequivocal evidence of any significant forcing by known solar variability[1,2]. Meadows[3] has traced the spotted and often confused history of such attempts, most of which were statistical tests of supposed connections between observed solar activity and various meteorological parameters. He adopted an earlier estimate[4] that "Solar activity does not produce a significant variation [upper limit of 0.1%] in the value of the solar constant". With this exclusion, any significant Sun–weather effects depended on indirect or 'trigger' mechanisms, which might result, for example, from perturbations in the energetically weak solar wind on the Earth's upper atmosphere and possible subsequent tropospheric response. Meadows concluded that: "If [an acceptable mechanism] could only be defined, the whole controversial field might be rapidly translated into the realms of high respectability".

We discuss here recent evidence for measured variations in the solar luminosity which provide a direct and simple mechanism for associated climatic change. Such variations, though small in amplitude, constitute a significant breakthrough in solar–terrestrial physics: for the first time a form of solar variability has been identified that is sufficiently energetic to alter directly the basic radiation balance of the lower atmosphere. Moreover, a wholly consistent response in surface temperature has already been (independently) identified[5], lending credence to the reality of the connection. The resultant changes in surface temperature are very small—no more than a few tenths of 1 °C. But the existence of a probable response opens the door to the possibility of larger effects, due to longer and more important changes in the bulk radiative output of the Sun.

Observational evidence for solar constant changes

Precision measurements of the total solar flux, or 'solar constant', *S*, have long been desired; they have become possible on a continuous basis only in the present decade with sophisticated radiometers in Earth orbit. Langley had foreseen the need to rise above the atmosphere 80 yr ago when he called for the establishment of an elevated solar observatory[6]: "The Earth's temperature and the life of its inhabitants, both animal and vegetable, depend on the solar radiation. Yet we confess that even at this late day we do not know, with any certainty, what the total amount of solar radiation is, whether it is constant or variable, or what effect upon terrestrial life and temperature a given change in it would produce. Our ignorance of these fundamental things is largely, though not wholly, due to the variability of our own atmosphere, which prevents us from studying that of the Sun".

In 1881, Langley had attempted a precision measurement of the solar constant from the top of Mt Whitney, 14,495 ft. elevation. Subsequently, he and Abbot for many years tried to measure the solar constant from mountain tops but their measurements were still limited by uncertainties in atmospheric transmission to about ±1% [7]. In 1980, near the peak of the

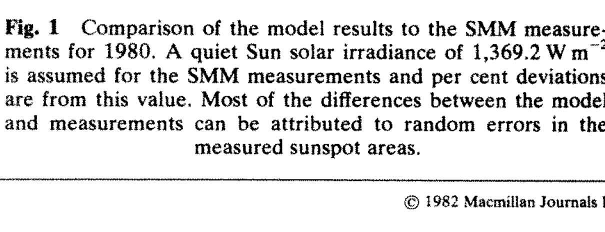

Fig. 1 Comparison of the model results to the SMM measurements for 1980. A quiet Sun solar irradiance of 1,369.2 W m^{-2} is assumed for the SMM measurements and per cent deviations are from this value. Most of the differences between the model and measurements can be attributed to random errors in the measured sunspot areas.

0028-0836/82/510689—05$01.00

solar activity cycle, the SMM spacecraft succeeded in accumulating nine months of continuous measurements of the solar constant with an unprecedented internal precision of 0.01% [8]. In these data was clear evidence of changes at the level of 0.1–0.3%, about an order of magnitude lower than the threshold of previous, ground-based measurements. A similar radiometer on the Nimbus 7 spacecraft[9,10] confirmed that these excursions, lasting 1 to 2 weeks, were depletions in the total output of the Sun. With these data the possibility of a rigorously constant *S* was unambiguously disproven for the first time.

Theoretical understanding of solar constant changes

The continuous solar constant measurements accumulated by the SMM in 1980 are shown in Fig. 1, as daily averages. Error bars are approximately the width of the line used to trace the record. It is obvious that the variations of *S* seen by the SMM are not those of a white noise spectrum, but are well approximated by a steady background with minor rises and major, superposed dips of varying amplitude. The time series of Fig. 1 suggests a process by which *S* is depleted over time scales of days to weeks without a compensating emission process. Moreover, initial analysis of the SMM data established the fact that the major dips were always coincident with the passage of large sunspot groups across the solar disk.

Sunspots are localized regions on the solar surface which appear dark in relation to the background solar photosphere (Fig. 2). The umbra, or dark central region of a sunspot, has a temperature of about 4,000 K, some 1,800 K or 30% cooler than the adjacent photosphere. A sunspot penumbra has a typical temperature of about 5,400 K.

Sunspots are regions of intense, concentrated magnetic field. These strong magnetic fields inhibit the local, vertical, convective transport of energy, leading to a lower, local radiative flux and a corresponding reduction in local temperature. It has long been suspected that the presence of sunspots, which are known to follow an 11-yr recurrence cycle, could modulate the Sun's total radiative output. In serious question, however, has been whether solar activity would decrease[11] or increase[12,13] the total solar flux, because dark sunspots are always accompanied by bright (hotter) facular regions in the photosphere and chromosphere. A third and equally tenable hypothesis was that a detailed balance in *S* would ensue between sunspot depletion and facular emission, resulting in a rigorously invariant solar constant. The SMM and Nimbus measurements establish that only a small fraction of the energy blocked by sunspots is balanced by immediate enhanced emission from bright features such as faculae and plages[8,14–16]. On time scales of months or years, there is no detailed balance. As we shall see, this fact has practical consequences for the effect of solar variability on the Earth's temperature.

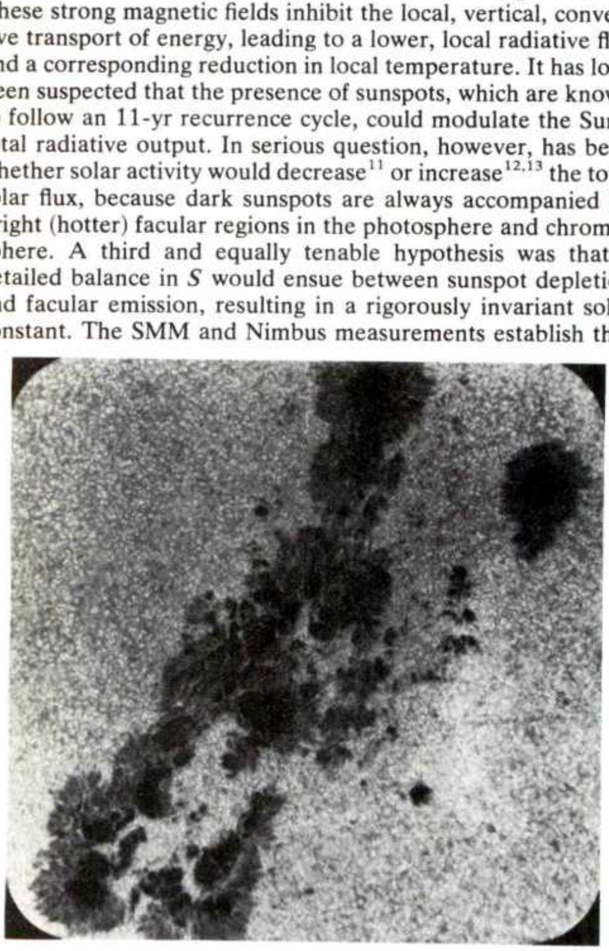

Fig. 2 A large sunspot group showing dark umbral and intermediate penumbral regions contrasted against the brighter surrounding photosphere. (Sacramento Peak Observatory, Association of Universities for Research in Astronomy, Inc.)

The basis for these important conclusions is the success of simple, blocking models in replicating the observed pattern of fluctuations in *S* that were observed with the SMM and Nimbus spacecraft (Fig. 1) using daily, observed values of projected areas and positions of sunspots made by ground stations. The symmetric, gaussian shapes of the major dips are readily explained as the result of spherical projection: a sunspot of fixed size will block more of the apparent area of the solar disk as solar rotation carries it towards the Sun's central meridian. Furthermore, the magnitude of the observed depletions in *S* are well duplicated by measured sunspot areas and canonical values of umbral and penumbral contrasts.

Schatten *et al.*[17,18] have endeavoured to attribute considerably more of the observed fluctuations in *S* as due to facular brightening, thereby implying a detailed balance in the total solar flux. This divergent interpretation is challenged by other, independent studies of the same spacecraft data[8,14,15,16,19–21]. As explained elsewhere[22,23], the discrepancy may be due to the failure of studies implying detailed balance to make use of actual, daily observations of sunspot and facular areas or to utilize the full SMM solar constant record. When this is done a better fit and a more accurate interpretation is obtained. The difference in terms of the storage of radiative flux within the Sun and in terms of potential climate effects is fundamental.

The model for sunspot blocking used in Fig. 1 is based on daily measured positions and areas of sunspots and on standard umbral, penumbral and facular contrasts of −0.75, −0.25 and +0.03 respectively[14]. Also included is the well-known effect of limb-darkening. The brightness of the apparent disk of the Sun decreases towards the edge, or limb; as a consequence sunspots near the limb have lower contrast relative to the background Sun than they do near the centre of the disk. The amount of irradiance blocked by a sunspot therefore decreases as it moves away from the apparent centre line, seen from the Earth, due to a combination of geometrical foreshortening and limb darkening. The model used in Fig. 1 also assumes that the blocked radiation is never released. In time it must be, but with the data now available it is possible only to conclude that the blocked energy does not reappear in recognized form for time scales of at least months, and probably a year. Continued measurements should help to refine the estimate of effective storage time. The notion of a frustrated Sun, with stored, and gradually released energy from remembered sunspots is not an altogether unreasonable one. Blocked, radiative energy can be stored in mechanical form in the lower convection zone with a relaxation time of up to 10^5 yr, (refs 24–26) during which time it will only slowly seep out. For purposes of comparisons with SMM or Nimbus data a storage time of this length is almost infinity.

The remarkable fit of SMM observations with simple, sunspot blocking models allows us to take two further steps. We can now predict the short-term excursions in *S* (should climatologists want them) a few days in advance, based on easily obtained measurements of sunspot areas and positions and the known rotational properties of the Sun. By the same technique we can also reconstruct the past history of daily fluctuations in *S* from archived sunspot data. Precise records of sunspot areas and positions exist for more than 100 yr. Figure 3 shows reconstructed, daily records of *S* for four sample years as they were generated from historical sunspot records[14]. The 108-yr reconstruction shows the expected signature of the 11-yr sunspot cycle, with greater accumulated depletion during years of enhanced sunspot numbers.

These predictions and reconstructions tell all we know with certainty of solar constant excursions. But there may well be more to the story in the form of longer, possibly independent

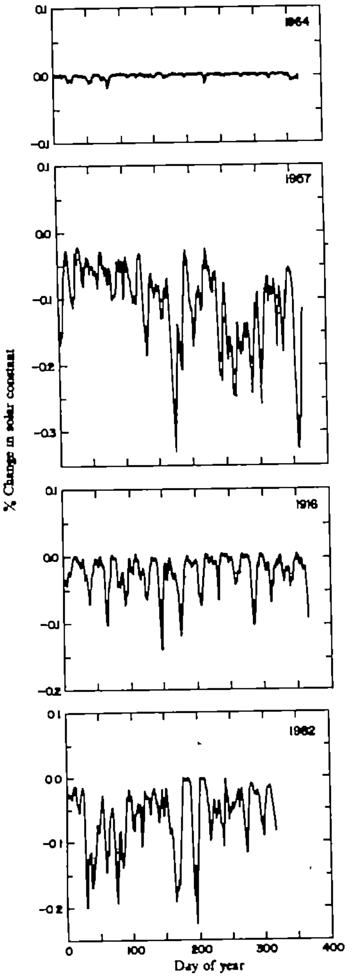

Fig. 3 Daily solar constant values reconstructed from sunspot and facular area records for sample years of low activity, high activity and recurrent, moderate activity with a similar reconstruction for 1982, to 14 November.

trends. Such trends, if they exist, could be of greater climatic impact, through persistence, than the short-term sunspot blocking effects noted above. The existence of one such possible trend, an apparent decrease in S of ~0.02–0.04% yr^{-1}, has already been noted in the Nimbus[27] and SMM[28] records. The model shown in Fig. 1 would predict a downward trend of about this amount in the 1979–82 period due to an averaged increase in sunspot areas during this time, even though sunspot numbers were simultaneously decreasing. It is probably too early, however, to determine whether the measured trend is real, and, if real, how much of it is due to accumulated sunspot blocking or some other effect.

We may sum up the recent discoveries concerning the solar constant as follows:

(1) The solar constant varies.

(2) The fluctuations are almost wholly explained by the simple mechanism of sunspot blocking, by which S is reduced in direct proportion to the fraction of the apparent solar disk that is covered by sunspots.

(3) Excursions in S during high solar activity are at most 0.5%, and more generally 0.1% or less, maximizing in each case when large sunspot groups are near the central meridian.

(4) Excursions of this nature persist throughout the period of visibility of the spot—for 14 days or less.

(5) The radiation blocked by sunspots does not immediately reappear where it can be seen or sensed; it is in some way stored within the Sun, to seep out much more slowly as an integrated increase in radiative flux.

(6) Photospheric and chromospheric faculae (surface regions brighter than the background disk) play at most a minor role in modulating the instantaneous value of S.

Evidence for a solar cycle effect in temperatures

A possible, 11-yr signal due to sunspot effects has long been sought in both regional and globally-averaged surface temperature records[29–34]—a search that has origins in ancient weather lore[35] and in literature[36,37]. The lack of any clear success in these attempts almost certainly implies that any globally distributed, coherent variation due to sunspot-cycle forcing must have a small amplitude. Still possible, however, are enhanced, regional or seasonal responses in areas of extended land mass and lower thermal inertia. Currie[5] has found statistically significant evidence for such a variation of annual-averaged surface temperature in 53 stations in the northeastern sector of North America, based on recent analyses of 80 yr of surface data. The varation found by Currie has a mean amplitude of about 0.18 °C; it was absent or undetectable in other regions of North America for which extended records exist. The mean period of the temperature variation was 10.5–10.7 yr, which may be compared with the mean sunspot blocking period shown in Fig. 4 of ~10.6 yr. Currie found that the air temperature lagged sunspot numbers by 5.7±0.7 yr in the sense that temperatures tended to be lower at maxima in the 11-yr sunspot cycle; this is almost precisely what would be expected were the temperature effect due to sunspot blocking, with a reduced solar constant at times of high sunspot numbers. The apparent confirmation of a suspected regional, solar–climate effect is intriguing; before it can be accepted, however, it should be tested on other continents and with realistic climate models. But a small solar constant signal, restricted to an inland region geographically removed from the thermal inertia of the oceans and downwind of a major mountain chain is not unreasonable.

We have found further possible evidence in the same geographical region by examining the occurrence of temperature extrema in a data set[38] of mean monthly temperatures for the 48 contiguous US states over the time span 1900–80. The occurrence of a monthly high temperature record was a factor of 3 more frequent during the three years of minimal sunspot blocking than during the three years of maximum sunspot blocking. The same effect is found in the remaining regions of the continental US although with a slightly weaker signal. This factor of three greater probability of finding temperature maxima at minimum solar activity is a statistically significant result, with only a 1% probability of occurring by chance. The corresponding occurrence of record low temperatures during maximum sunspot blocking has a much weaker mirror relationship: record low temperatures were 30% more frequent in maximum than in minimum sunspot blocking years, although there is a 20% probability of this having occurred by chance.

Theoretically expected temperature response

What global surface temperature response should we expect from the reconstructed solar constant forcing? A reasonable answer is shown in Fig. 4, from a simple global climate model that assumes energy balance between incoming solar radiation and outgoing IR[39,40]. The model includes terms for the thermal inertia of the oceans: a mixing layer (upper level equivalent 87 m of water) with a thermal response scale of 5–10 yr, and a deep ocean with a volume 20 times larger. The effect of a

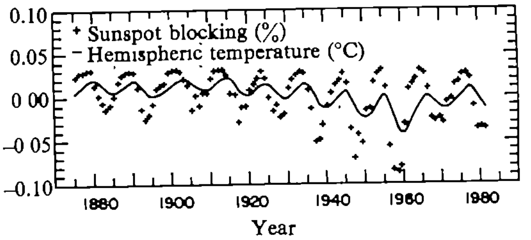

Fig. 4 The yearly mean deviations in solar irradiance indicated by the sunspot blocking model for 1874–1981 with expected hemispheric temperature variations as calculated using a simple energy balance climate model.

short-term change in insolation will be moderated by the large thermal inertia of the strongly-interacting surface regions (atmosphere, land surface and ocean mixed layer) of the Earth. The degree of attenuation will depend on the frequency and persistence of the forcing signal. A cyclic perturbation in insolation with a period of 11 yr will induce a surface temperature response that is a factor of 2–3 smaller than the equilibrium response to the same forcing. The equilibrium response of surface temperature to solar constant changes is generally estimated at 0.1 °C for a 0.1% radiative perturbation[41]. Peak-to-peak variations in solar forcing of 0.12% on an 11-yr cycle derived from extrapolated sunspot blocking models will lead to a similar cycle in mean global temperature with an amplitude of only 0.06 °C. Possible feedback mechanisms make this estimate uncertain by a factor of at least 2, but more detailed calculations of atmospheric circulation tend to support the energy balance arguments given above.

The atmosphere itself has a thermal inertia time scale far shorter than 1 yr (as evidenced by diurnal and seasonal variations). Therefore an inland region that is isolated from ocean temperature moderation can react to solar forcing in a manner more nearly that of the theoretical equilibrium response. Regions at high latitude will also experience larger responses due to the positive feedback of snow-albedo in which decreased solar radiation leads to greater snow cover, hence higher albedo and an even lower surface temperature. Currie's finding[5] of a weak, 11-yr cycle in inland North American air temperatures is therefore consistent in period, phase and amplitude with that expected theoretically from reconstructed sunspot blocking[14].

One can also test the compiled record of annual mean Northern Hemisphere temperature[42] for evidence of the same effect. We have done so and find that the mean hemispheric temperature during 1881–1981 was on average 0.036 °C cooler in the 3 yr of peak sunspot blocking as compared with the adjacent 3 yr of minimum solar activity. The reconstructed solar constant for the same period exhibits mean peak-to-peak variations of 0.06%; hence the observed temperature change is almost exactly what one should expect for a hemispheric average, based on simple climate models. Unfortunately, as is so often the case in solar–climate studies, the finding just cited is not statistically significant—about 50% of the time, given the statistics of the population sample, the same correspondence could occur from mere chance.

The response of surface temperature to forcing by sunspot blocking can be summarized as follows:

(1) On a hemispheric or global scale surface temperature responds to the 11-yr sunspot cycle, with an amplitude of 0.036 °C. However, this variation, although in accord with predictions of simple climate models, is not statistically significant.

(2) Station records for the past 80 yr in the north-east sector of the US establish that the mean surface temperature responds to solar, 11-yr forcing with an amplitude of a few tenths of 1 °C.

(3) A significant variation in the temporal distribution of record high monthly mean temperatures occurs in the same geographical region cited above, in response to solar forcing. The number of record low monthly mean temperatures also responds in a manner consistent with solar forcing, but not in a statistically significant way.

The phase of the relationship between sunspots and the solar constant, described above, is precisely opposite that which has been proposed to link longer-term changes in the envelope of solar activity with century-scale changes in climate[43]. The possible association of the Maunder and Sporer minima of solar activity, lasting 70 and 130 yr, with coincident cold periods of the Little Ice Age has been interpreted, for example, as the result of a postulated drop of about 1% in the solar constant[44]. The simple extrapolation of the mechanism of sunspot blocking to century-scale changes in the envelope of the activity cycle would induce an apparent secular modulation of at most 0.1%, with an increased solar constant at times of suppressed activity, such as the Maunder Minimum. Whether such an extrapolation is justified is another question. It is altogether possible that solar processes other than accumulated sunspot blocking act to modulate the solar constant in the longer term, and that such processes could oppose, in sense, the higher frequency modulation due to the 11-yr sunspot cycle. Such long-term changes are, of course, wholly speculative, since precision measurements of the solar constant span no more than 4 yr.

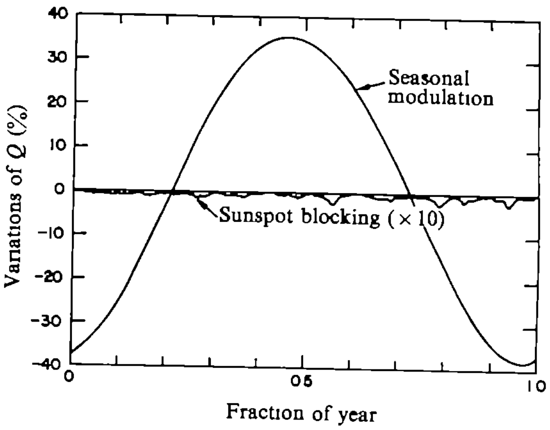

Fig. 5 Variation of daily solar irradiance (represented by Q) about the yearly mean due to seasonal effects in per cent deviation from a hemispheric average. The solar constant reconstruction for 1981 is shown multiplied by a factor of 10 for comparison.

Importance of climatic response

As shown above, both observation and theory seem to support the case for a small but direct surface air temperature response to measured and extrapolated solar constant fluctuations that is within a factor of 2 of the expected change in the solar luminosity.

These conclusions suggest several practical questions: (1) Is the apparent temperature response detectable as a perceptible weather effect? That is, can the average person sense a solar constant perturbation? (2) Will the anticipated climatic change be significant in practical or economic terms? (3) Can identifying the cause of climatic change at this level lead to better weather prediction?

Considering that the amplitude of the solar-induced mean temperature signal is but a few tenths of 1 °C, the answer to all of the above questions must surely be negative. A surface temperature effect of this magnitude is truly insignificant and for practical purposes imperceptible in the presence of typical diurnal extremes of 10° and a seasonal range of at least 30°. It is hard to see how a cyclic variation of a few tenths of a degree in the mean could have either predictive or economic import.

However, a factor of 3 enhancement in the frequency of temperature maxima occurring over a sunspot cycle could yield a marginally positive answer to all three of our pragmatic questions. People are much more likely to notice and remember unusual climate extremes. In economic terms it is again the extremes which cause dislocations. A factor of 3 change in the probability of occurrence of extrema in temperature is also of possible though limited predictive power.

Another way of gauging the climatic importance of a small perturbation to the solar constant is to compare it with the seasonal cycle of insolation. In Fig. 5 we compare the intra-annual variation of daily sunlight received over the Northern Hemisphere with the variation of S as reconstructed from sunspot blocking for 1981 (the latter is multiplied by 10 to make it visible). As one can see the interannual variation due to seasonal effects easily overwhelms that due to sunspot blocking. As another test, if we define the onset of spring to be 21 March in a year with 'normal' solar irradiance, how much will anticipated insolation changes due to sunspot blocking shift the effective first day of spring? In a year with high sunspot blocking (such as 1981 or 1982) the integrated irradiation reaches that of a normal spring about 0.2 days late. One effect of a sunspot-blocked solar constant could thus be the delay of the onset of spring by a few hours. By comparison, the meteorologically defined onset of spring, the date of last severe frost, has a typical variation of about 21 days and extreme differences of about 90 days in mid-latitude regions. Hence any shift due to the solar constant sunspot blocking is unimportant compared with typical variations, just as any induced change of mean surface temperature is also small compared with typical variations. This could be qualified, perhaps, by the fact that the mean sunspot blocking effect extends over a few years, thus allowing seasonal variations to be averaged over, making it slightly easier to detect the small effect.

Discussion

Solar constant variations of at most 0.5% for a few days and ~0.1% for a few years are now known to exist, but their expected effects on surface temperature are by any measure minor. Modelled or measured climate responses are insignificant compared with normally occurring changes and to apparently random variations in temperature. Thus it seems wholly unjustified to attribute the coincidence of a harsh winter such as that of the past year in some regions to a direct effect of a coincident solar constant deficit[28].

On the other hand, the importance of climate responses which might result from solar constant variations should not be dismissed. The identification of a simple, external forcing function such as a variable solar constant, which induces detectable changes of mean temperature, however slight, may provide a practical test of climate sensitivity on regional scales. Climate sensitivity verification is crucial to understanding such problems as the impact of anthropogenic carbon dioxide increases and land use changes. In a world where the demand for food is ever closer to the available supply, it may be true that any predictable fluctuation in climate will in time become important.

Perhaps the most important conclusion of the variations now established in the solar constant is that the Sun is indeed variable in its most fundamental output and that plausible responses of surface temperature have now been at least tentatively identified. Thus to increase our understanding of solar variability, we must continue the precision monitoring of the outputs of the Sun.

The demonstrated connection between changes in the solar constant and surface temperature exemplifies the kind of effort needed to redirect the study of solar–terrestrial relationships. Precision, spaceborne measurements of the solar output have enabled us to identify, and delimit, at least on time scales of days to years, a real climatic effect. Important questions remain unanswered. What are the detectable impacts of measured changes in solar short-wave radiation, or in the variable, particle inputs to the upper atmosphere? Do 'trigger' mechanisms have a role in amplifying the effects of variations in S or in other, weaker outputs of the Sun? Is the solar constant variable, perhaps in different or opposing ways, on longer time scales? New attempts at answering these and other such questions must surely focus not on statistical correlations but on mechanisms, modelling, and above all, measurements. Until we know how and in what ways the Sun varies we can only guess the possible terrestrial consequences.

The 5-min oscillations of the Sun are incompatible with a rapidly-rotating core

R. H. Dicke

Joseph Henry Laboratories, Physics Department, Princeton University, Princeton, New Jersey 08544, USA

Hill's suggestion that Einstein's general relativity may be invalid requires a rapidly spinning solar core. The triplet structure observed in the solar 5-minute power spectrum seems incompatible with this rotating core. But the triplet structure can be accounted for as the effect of a magnetically distorted core rotating with a ~12.5-day period.

FROM a study of the fine structure of solar oscillations Hill[1,2] has concluded that the Sun's core is rotating with a period of ~4 days. From a consideration of the effect of the resulting J_2 on Mercury's motion he concludes that Einstein's general relativity may be invalid[1]. From the same data Gough[3] agrees that the Sun contains a rapidly rotating core, but he disagrees with the implication *vis-à-vis* Einstein's theory.

0028-0836/82/510693—05$01 00

An even shorter rotational period (1 to ~2 days) was previously obtained from solar oblateness measurements (a P_2 distortion) made in 1966[4,5]. It was later found that a substantially better fit to the data could be obtained from an alternative hypothesis, that the solar distortion is not axially symmetric and that the distorted solar figure (the gravitational potential surface) rotates rigidly over the solar surface, as a wave, with a 12.38±0.10-day period (sidereal)[6,7]. It has been suggested that the 12.38-day period represents the rotational period of the core and that the distorted gravitational potential is due to a strong magnetic field buried in the solar core[7–9].

Clearly the 4-day period of Hill *et al.* and Gough, and this 12.4-day core rotation period are incompatible. Which if either is correct? The triplet structure discovered by Claverie, *et al.*[10] in the $l = 1$ '5-min' oscillations may yield the answer (see Fig. 1).

This triplet structure was first interpreted as rotational splitting of the $m = 1, 0, -1$ components of the $l = 1$ modes, the effect of advection of the modes[10]. With this interpretation the splitting is too small to be compatible with the ~4-day period and with the rotational curves given by Gough[3]. It yields a core rotation period of ~12 days for a rigidly rotating core with a radius of 0.6.

Isaak[11] has noted that owing to the symmetry of the observation, an average over the solar disk, the central ($m = 0$) component of the triplet (Fig. 1) should be missing for a solar axis perpendicular to the line-of-sight. For the actual solar axis tilt ~6° the $m = 0$ component should be very weak, with an intensity of 0.005. Isaak has suggested that the axial symmetry of the sun is broken by an off-axis magnetic field in the solar core rotating with a 12-day period and that the '$m = 0$' component is present because it contains an admixture of $|m| = 1$ induced by the magnetic field.

Gough[12] has noted that the same symmetry requirement would yield a triplet structure for rotational splitting of the $l = 2$ oscillations (without $m = \pm 1$ components), but he considers an $l = 2$ origin of the triplet implausible. With an $l = 2$ origin and the splittings given above (Fig. 1), the core of the Sun must rotate slower than the surface. This is very unlikely. Furthermore, Gough[12] considers the $l = 1$ identification to be statistically robust.

The fine structure of the $l = 1$ '5-min' oscillation seems to be incompatible with a purely rotational splitting induced by a rapidly rotating core. Is it compatible with the type of splitting to be expected from a magnetized solar core rotating rigidly with a 12-day period? Gough[12] has already examined this question making several simplifying assumptions and found that he could not obtain a satisfactory account of the splitting using this solar model.

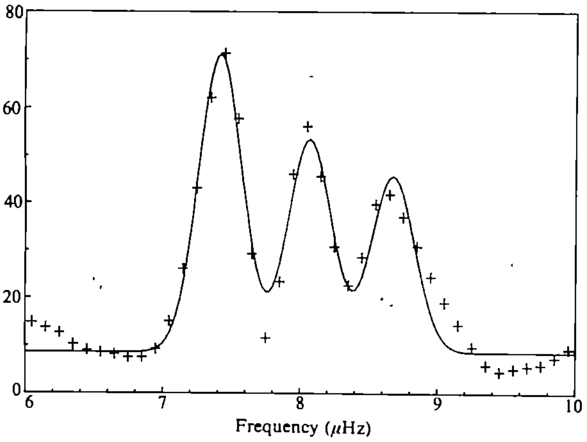

Fig. 1 Fine structure of $l = 1$ modes of '5-min' oscillations. The data points were taken from Fig. 2*b* in ref. 10. (The frequency origin is arbitrarily chosen.) The curve is an eight-parameter fit of the sum of a constant and three gaussians having a common width. The three frequencies obtained are: $\nu_1 = 7.419 \pm 0.009$, $\nu_2 = 8.071 \pm 0.012$ and $\nu_3 = 8.676 \pm 0.015$ μHz. The two frequency splittings differ by only 1.6σ. The mean splitting is 0.6285± 0.0087 μHz. The errors are only formal standard deviations. The gaussian width (σ) is 0.158 μHz.

Table 1 Matrices $R(\alpha)$, $P(\beta)$ and T

$\begin{bmatrix} \cos\alpha & -\sin\alpha & 0 \\ \sin\alpha & \cos\alpha & 0 \\ 0 & 0 & 1 \end{bmatrix}$	$\begin{bmatrix} \cos\beta & 0 & \sin\beta \\ 0 & 1 & 0 \\ -\sin\beta & 0 & \cos\beta \end{bmatrix}$	$\begin{bmatrix} & -1 & i & 0 \\ \frac{1}{\sqrt{2}} & 0 & 0 & \sqrt{2} \\ & 1 & i & 0 \end{bmatrix}$

Elements of the rotation matrices $R(\alpha)$ (z axis), $P(\beta)$ (y axis) and the transformation matrix T (for change of basis from W_n to $Y_{1,m}$).

One of Gough's assumptions can be questioned. He correctly notes that both the perturbation of the wave by the magnetically distorted core and the rotationally induced advection of the propagating wave are small effects and can be linearily superposed. He consequently assumes that the normal mode structure can be calculated by first neglecting the effect of solar rotation (including only the magnetically induced perturbation) and then adding the advection to this normal mode.

It is shown here that this assumption seems to be untenable. When the solar core is rotating more rapidly than the surface it is necessary to include the effect of advection before the normal oscillatory modes are calculated. Both the structure of the normal modes and their frequency perturbations can be strongly affected by advection.

Normal oscillatory modes

The normal modes for $l = 1$ are to be calculated assuming that the solar core (of radius r_c) is distorted by an internal magnetic field and is rotating rigidly with an angular velocity Ω_c. It is assumed that outside the core ($r_c < r < r_0$) $\Omega(r)$ is a function of r only. To avoid the complications arising in the time dependence of the magnetic perturbation we follow Gough's technique of employing a coordinate frame fixed to the core. The small Coriolis effect is neglected.

In this coordinate frame the solar core is static whereas the outer shell is rotating in a steady state. In the absence of dissipation the wave equation is time-reflection invariant in the core.

Expressed in terms of the radial displacement of the fluid ξ, the $l = 1$ unperturbed normal modes (complex) are conveniently separated into ingoing and outgoing waves, ξ_- and ξ_+

$$\xi_- = \sum_n a_n W_n(\theta, \phi) f(r) \exp(-i\omega t) \qquad (1)$$

$$\xi_+ = \sum_n b_n W_n(\theta, \phi) f^*(r) \exp(-i\omega t) \qquad (2)$$

(By an unperturbed normal mode is meant a normal oscillatory mode for a non-rotating Sun with an undistorted solar core.)

Near the centre of the Sun the complex radial function $f(r)$ has the form of the derivative of a spherical Hankel function

$$f(r) = -i \frac{d^2}{dr^2} (\exp(-ikr)/k^3 r) \qquad (3)$$

Elsewhere it depends on details of the solar model. $f(r) + f^*(r)$ is singularity free at $r = 0$. For the unperturbed normal mode the constant $b_n = a_n$. For the perturbed wave the (complex) a_n and b_n are functions of r.

The waves are expanded in real surface harmonics of $l = 1$ (W_n) which are in turn expressed in terms of the usual (normalized) complex spherical harmonics $Y_{l,m} \sim P_l^{|m|} e^{im\phi}$

$$W_1 = \frac{1}{\sqrt{2}} (-Y_{1,1} + Y_{1,-1})$$

$$W_2 = \frac{i}{\sqrt{2}} (Y_{1,1} + Y_{1,-1}) \qquad (4)$$

$$W_3 = Y_{1,0}$$

The real surface harmonics, W_n, are required to incorporate conveniently the time reflection invariance of the solar core.

The calculation of the three normal modes for $l=1$ and a fixed radial order is carried out in four steps:

(1) We start with the ingoing wave evaluated at the surface of the core and characterized by the three wave amplitudes a_1, a_2, a_3. The ingoing wave passes through the core and reappears at the surface as an outgoing wave characterized by b_1, b_2, b_3. Owing to the influence of the core magnetic field, the velocity of sound is not uniform on spherical surfaces and the wave propagating through the core undergoes an angle dependent phase shift. The outgoing amplitudes b_1, b_2, b_3 describe the $l=1$ part of this phase shift. The as and bs are linearily related. In matrix notation

$$b=Sa \tag{5}$$

where a and b are column vectors containing their three elements of the order (1)...(3). The so-called scattering matrix S is both unitary and symmetric. In the absence of the core distortion $S=I$ is the identity matrix.

(2) After leaving the core, the outgoing wave passes through the outer shell, is reflected at the solar surface and returns as an ingoing wave to the surface of the core where it has an amplitude a'. In this transit through the rotating shell the wave is rotated through a (negative) angle $\Delta\phi$ given by

$$\Delta\phi = 2\int_{r_0}^{r_0} (\Omega(r)-\Omega_c)\,\mathrm{d}r/c \tag{6}$$

where c is the sound velocity.

$$a' = R(\Delta\phi)\cdot b \tag{7}$$

where $R(\Delta\phi)$ is the rotation matrix which rotates b by $\Delta\phi$ into the orientation of a' (see Table 1).

(3) To represent a normal mode (a') must be identical with (a) except for the phase shift factor $\lambda = \exp(-i\Delta\omega\tau)$ due to shift $\Delta\omega$ in the angular frequency. Here $\tau \cong 7{,}400$ s is the round trip transit time of the wave. Combining equations (5) and (7) and setting $a' = \lambda a$ yields the eigenvalue equation

$$(RS)a_i = \lambda_i a_i \tag{8}$$

The matrix (RS) is unitary and its three eigenvalues λ_i are unimodular. For each of these eigenvalues there is an eigenvector a_v containing three components, representing one of the normal modes.

As seen from the Earth (synodic frequency)

Fig. 2 The computed fine structure of the $l=1$ component of the '5-min' oscillation of the Sun. The three phase angles of the scattering matrix, s_1, s_2, $s_3 = -0.0162$, -0.0081 and $+0.0242$, have ratios that differ only slightly ($\sim 1\,\sigma$) from the ratios of the three principal moments of inertia of the solar core. The mode advection angle is $\Delta\phi = -0.0167$ and the core orientation angles are $\alpha = 1.59$, $\beta = 0.787$ rad. The plotted frequencies are: (1) $\Delta\nu_i = -s_i/2\pi\tau$, for which the effect of advection is neglected ($\tau = 7{,}400$ s); (2) $\Delta\nu_i = \Delta\omega_i/2\pi$, equation (8), where the effect of advection $\Delta\phi$ is included but the mode is observed from the rotating core; (3) the same as (2) above but as viewed from the Earth (synodic frequencies) $\Delta\nu_{im} = (\Delta\omega_i + m\Omega_c)/2\pi$ with the spherical harmonic orders m and the line intensities labelled. The intensities are chosen to sum to unity for each mode. $\Omega_c/2\pi = 1/12.81\ \mathrm{day}^{-1} = 0.903\ \mu$Hz.

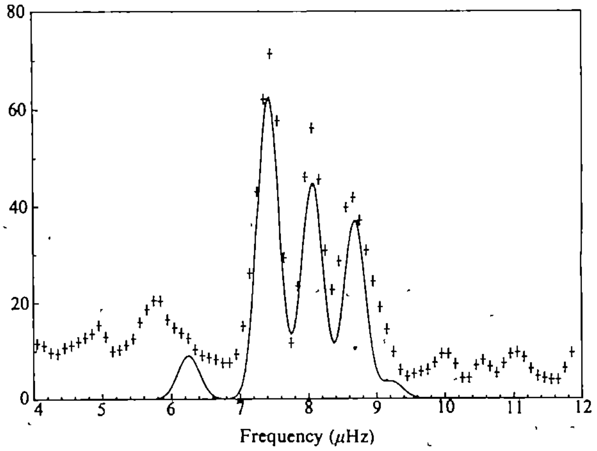

Fig. 3 Plot of the six spectral lines shown at the right of Fig. 2 against the data. The widths of the (guassian) lines are given by $\sigma = 0.158\ \mu$Hz.

(4) The above three values of $\Delta\omega$ would be observed in a coordinate frame rotating with the solar core. The transformation to an inertial coordinate frame is carried out by again using the rotational operator R. In inertial coordinates (primed) the ingoing wave amplitude (a_i) becomes

$$a_i' = R(\Omega_c t)a_i \tag{9}$$

This splits each normal mode (i) into three components with angular frequencies

$$\omega + \Delta\omega_i + m\Omega_c \tag{10}$$

of different order (m) spherical harmonics, $m = 1, 0, -1$. This is a purely kinematic effect (a rotational Doppler effect). In inertial coordinates the expansion (1) (2) in real harmonics is no longer convenient. Setting

$$\sum a_n W_n = \sum c_m Y_{1,m} \tag{11}$$

the spherical harmonic expansion coefficients c_m are obtained from the matrix equation

$$c = Ta \tag{12}$$

(see Table 1). Here the elements of c are of the order of $m = 1, 0, -1$. As seen from the Earth the (synodic) angular frequency is expression (10) with Ω_c replaced by $\Omega_c - 2\pi/365.25$ (day^{-1}).

The expression (10) divided by 2π yields nine different frequencies, three values of $m = 1, 0, -1$ for each normal mode $i = 1, 2$ and 3. But, as discussed above, the three $m = 0$ terms should be too weak to be observed. Depending on the scattering matrix S and the wave advection angle $\Delta\phi$ in expression (6) the remaining six frequencies can be of different intensities, some being so weak as to be unobserved.

The above discussed origin of the fine structure of the $l=1$ '5-min' normal modes is shown in Fig. 2 using the numerical example discussed below.

The scattering matrix

Evaluated at the surface of the core the intensity of the ingoing wave is proportional to $a\dagger a$, where $a\dagger = \tilde{a}^*$ is the Hermitian conjugate of (a). The outgoing wave intensity is $b\dagger b$ and for a lossless core $b\dagger b = a\dagger S\dagger Sa = a\dagger a$. This implies that $S\dagger = S^{-1}$, namely that S is unitary.

Because of time reversal invariance in the solar core, for any solution to the wave equation, $\xi(t)$, there is another $\xi^*(-t)$ and for the solution (a, b) there is another (b^*, a^*). Thus, $a^* = Sb^*$, $b = (S^*)^{-1}a$, $S = \tilde{S}$ and S is symmetric. Owing to these two properties of S, the matrix $i(S+1)(S-1)^{-1}$ is real. Thus its eigenvectors (and the eigenvectors of S) can be real and S can be diagonalized by an orthogonal matrix.

In the absence of a distortion of the core $S = I$ and for a first-order perturbation by a small core distortion, the correction to S is purely imaginary. This first-order correction to the outgoing wave amplitude (b) is calculated using Green's theorem, neglecting buoyancy effects.

$$\int [\eta \nabla_r \xi_1 - \xi_1 \nabla_r \eta] \rho c_0^2 r_c^2 \, d\Omega = \int_0^{r_c} \nabla \eta \cdot \nabla \xi_0 C \rho c_0^2 r^2 \, dr \, d\Omega \quad (13)$$

Here the left side is an integral over the surface of the core, ξ_1 is the first-order perturbation of the radial displacement, $c_0^2(r)$ is the unperturbed sound velocity squared, and $\eta = (f + f^*) W_n \exp(i\omega t)$.

The right side of equation (13) is an integral over the interior of the solar core, ξ_0 is the unperturbed radial displacement and the sound velocity (squared) is $c^2 = c_0^2(r)[1 + C(r, \theta, \phi)]$. The left side yields the perturbation of b_n and consequently the first-order correction to S. Only the $l = 2$ part of C contributes to the right side.

Any real second-degree spherical harmonic ($l = 2$) defines one or more sets of principal axes and can be expressed as a superposition of three second-degree Legendre polynomials, $P_2(n) = \frac{1}{2}(3 \cos^2 \theta_n - 1)$, referred to these three principal axes. The $l = 2$ part of the sound velocity anisotropy $C(r, \theta, \phi)$ can be expressed as

$$C_2(r, \theta, \phi) = h(r) \sum_{n=1}^{3} c_n P_2(n) \quad (14)$$

where $\sum_n c_n = 0$.

The right side of equation (13) is easily evaluated with the core first oriented to bring its principal axes into coincidence with the three coordinate axes. Equation (13) then yields a diagonal first-order perturbation of S with elements is_n. The diagonal matrix is designated as S_d, and has the eigenvalues $S_n = \exp(is_n)$ on its diagonal with $s_1 + s_2 + s_3 = 0$.

Substituting equation (14) in (13) and using the WKB approximation gives

$$s_n = -\frac{4\omega c_n}{5} \int_0^{r_c} h(r) \frac{dr}{c_0(r)} \quad (15)$$

To obtain the scattering matrix for the core in its proper orientation, the core is first rotated about the z axis through an angle α, then about the y axis through an angle β and finally again about the z axis. The last rotation can be omitted because it is equivalent to a rotation of the arbitrarily oriented coordinate system about the z axis. The scattering matrix of the reoriented solar core is

$$S = P(\beta) R(\alpha) S_d \tilde{R}(\alpha) \tilde{P}(\beta) \quad (16)$$

(see Table 1 for $P(\beta)$). As noted above, S can be diagonalized by an orthogonal matrix, in this case the matrix (PR).

A magnetic field in the solar core perturbs the velocity of sound in several different ways, primarily by perturbing the fluid density and pressure, and by the magnetic pressure. For a magnetic field which is primarily toroidal and derived from a spherical harmonic of definite degree (l), all of these contributions to the function $C(r, \theta, \phi)$ have the same angular dependence[9]. This angular dependence can be obtained from the principal moments of inertia of the core which are in turn obtained from the $l = 2$ part of the distortion of the solar surface[7].

Under a hypothesis to be discussed elsewhere the $l = 2$ part of the surface distortion can be calculated and yields -1.33 ± 0.23, -0.36 ± 0.22 and 1.69 ± 0.15 ($\times 10^{50}$ g cm^2) for the three (traceless) principal moments of inertia of the solar core. (The significance of these results for the nutation and the oscillation of the core is to be discussed elsewhere.) If the above assumptions are valid the three eigenvalue phase angles s_i should be proportional to the above three traceless moments of inertia (I_i) namely

$$s_i / s_j = I_i / I_j$$

and

$$s_i = K I_i \quad (17)$$

Numerical results

Is the fine structure splitting seen in the series of $l = 1$ '5-min' oscillations compatible with a magnetically distorted core rotating with a 12.38-day period (sidereal) as derived from the 1966 observations[5] of the 'solar oblateness'? Owing to the nutation and a possible long-period oscillation[9] expected with a magnetically-distorted core, the core orientation obtained from the 1966 data is not expected to be valid in 1981, but the eigenvalue phase angle ratios in expression (17) are assumed to be applicable with a 1 σ accuracy. With these restrictions the multiplier K in equation (17) and the angles α, β and $\Delta\phi$ are assumed to be freely adjustable.

By adjusting these four parameters the following conditions should be met: (1) the intensities of the six frequencies with $m = \pm 1$ should divide into three intense spectral lines and three negligible weak ones; (2) the intensity ratios of the strong lines should be acceptable; and (3) their frequency differences should be correct. The example illustrated in Fig. 2 with the parameters given in the caption is considered to be satisfactory. There is no *a priori* reason for the three normal modes to be equally excited and the indicated intensities (assuming a total intensity of 1 for each normal mode) are satisfactory.

In Fig. 3 the six spectral lines shown in Fig. 2 are plotted with the data after adjusting the total intensities of the three normal modes to be in the ratios of 0.985/1.000/0.807 in order of increasing frequency $\Delta\omega_i / 2\pi$.

Conclusions

With the assumption that the solar rotation outside the core is substantially uniform, the advection (rotation) angle $\Delta\phi = -0.0166$ permits a calculation of the radius of the core using equation (6). The core is found to have a radius half that of the Sun (3.5×10^{10} cm).

Assuming a distorted mass shell of this radius and the principal moments of inertia given above yields a $\delta\rho/\rho$ contribution to the values of $s_1 \ldots s_3$ with magnitudes roughly 1.8 times the above, but with opposite sign. Owing to the important role of the magnetic pressure and the distorted gas pressure, which contribute with signs opposite to $\delta\rho/\rho$, it is impossible to obtain better estimates for s_i without knowing more about the distribution of the magnetic field.

Apparently a magnetically distorted solar core rotating with

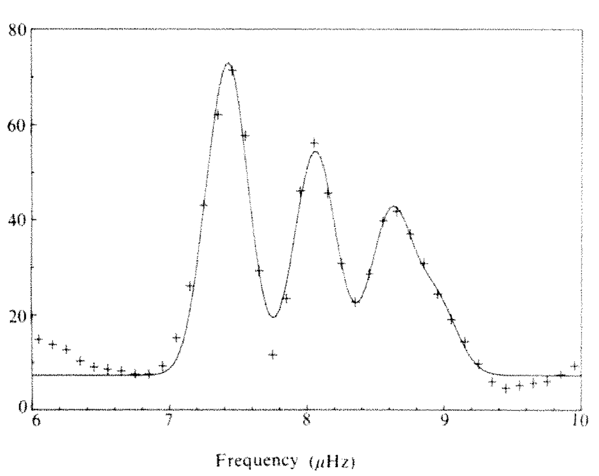

Fig. 4 Same as Fig. 1 but including four gaussians in the least-square-fit to the data points. In order of increasing frequency the intensity and frequency of each of the three spectral lines are 65.7 ± 2.0, 7.420 ± 0.006 μHz; 47.2 ± 2.0, 8.063 ± 0.008; 33.9 ± 2.7, 8.613 ± 0.018 and the fourth weak peak of unknown cause are 15.1 ± 2.7, 8.941 ± 0.039. The difference between the two principal frequency separations is 0.093 ± 0.025 μHz. Thus the two frequency splittings are unequal at a 4σ level.

a 12.38-day period can give a satisfactory account of the triplet structure of the $l=1$ '5-min' oscillations. But there is one unsatisfactory feature in the above account. The three gaussians fitted to the data in Fig. 1 give equal line splittings for the triplet to within 2σ. But, from the standpoint of the above analysis this is a fortuitous result. We have no explanation for the equality.

But are the splittings between the three spectral lines actually equal? An examination of the high frequency component in Fig. 1 shows a poor fit to the data. There appears to be a blend with some unidentified weak fourth line, perhaps due to noise or aliasing. By adding a fourth gaussian a satisfactory fit to the high frequency component is obtained (see Fig. 4). Now the splittings of the three principal components are unequal at a statistically significant level (4σ).

For the above interpretation of the $l=1$ fine structure to be valid, the fine structure would be expected to vary significantly in a year or two, owing to nutation and/or torsional oscillation[9] of the core.

Garnet–orthopyroxene barometry for granulites and peridotites

S. L. Harley* & D. H. Green

Department of Geology, University of Tasmania, Hobart 7000, Australia

An experimentally calibrated geobarometer based on the solubility of alumina in orthopyroxene coexisting with garnet is presented. This geobarometer is based on experiments in the $FeO–MgO–Al_2O_3–SiO_2$ *and* $CaO–FeO–MgO–Al_2O_3–SiO_2$ *systems performed at high temperatures and pressures (800–1,200 °C and 5–20 kbar). Applying the geobarometer to a variety of natural garnet–orthopyroxene assemblages from granulite facies terrains and other occurrences, yields reliable and consistent pressure estimates for these samples.*

PETROLOGISTS concerned with garnet peridotite xenoliths in kimberlitic diatremes have long recognized the importance of the solubility of alumina in orthopyroxene coexisting with garnet as a pressure (P)–temperature (T) indicator[1–4]. More recently, petrologists have applied the garnet–orthopyroxene geobarometer to estimate the physical conditions of equilibration of crustal granulites[5,6]. Earlier experimental calibrations of the variation in the alumina content of enstatite coexisting with pyrope as a function of P and T in the system $MgO–Al_2O_3–SiO_2$ (MAS) have been used widely, in conjunction with other geothermometers, to construct 'palaeogeotherms' for mantle-derived garnet peridotites[7–11]. More recent experimental data in the system $MgO–Al_2O_3–SiO_2$ (refs 12–16) have tended to confirm the $P–T$ dependence of alumina in enstatite coexisting with pyrope that was obtained by MacGregor[7]. Recent results in $CaO–MgO–Al_2O_3–SiO_2$ (CMAS)[13,17] have, however, necessitated a revision in pressures estimated from alumina contents of orthopyroxenes coexisting with pyrope–grossular garnets such as those which occur in garnet peridotites. Major problems encountered in the application of these experimental studies undertaken in simple end member systems to natural rocks, are the effect of the Fe^{2+} contents of the phases on the alumina solubility at any given $P–T$ condition, and the lack of adequate experimental data at $P–T$ conditions directly applicable to natural granulite assemblages. Previous experimental studies in Fe-bearing systems[5] have been restricted in the compositional range studied, and have yielded only unreversed data for the alumina contents in orthopyroxenes coexisting with a garnet phase. For these reasons, and because of the widespread occurrence of garnet–orthopyroxene assemblages in crustal granulites, we have experimentally recalibrated the garnet–orthopyroxene geobarometer/geothermometer in the $FeO–MgO–Al_2O_3–SiO_2$ (FMAS) and $CaO–FeO–MgO–Al_2O_3–SiO_2$ (CFMAS) systems, over a wide range in X_{Mg} (Mg/Mg+Fe) and X_{Ca}(Ca/Ca+Mg+Fe) bulk compositions at any one $P–T$ condition, and at $P–T$ conditions appropriate to the formation of crustal granulites (800–1150 °C and 5–20 kbar).

Thermodynamic treatment of garnet–orthopyroxene equilibria

The reaction buffering the alumina content of orthopyroxene coexisting with garnet may be written as[5,7,14]:

$$\begin{array}{ccccc} Mg_2Si_2O_6 & + & MgAl_2SiO_6 & = & Mg_3Al_2Si_3O_{12} \\ \text{Enstatite} & & \text{Mg-Tschermaks'} & & \text{Pyrope} \\ \text{component} & & \text{component} & & \text{in garnet} \\ & & \text{Orthopyroxene} & & \end{array} \qquad (1)$$

Reaction (1) above is useful for geobarometry because of the large volume change involved ($=200$ cal kbar^{-1} mol^{-1}).

The equilibrium condition for reaction (1) at a given pressure, P, and temperature, T, is:

$$\Delta H^\circ - T\Delta S^\circ = RT \ln (a^{op}_{En})(a^{op}_{MgTs})/(a^{ga}_{py}) - P\Delta V^\circ \qquad (2)$$

where ΔH° and ΔS° are, respectively, the enthalpy and entropy changes of reaction (1); ΔV° is the standard molar volume change of reaction (1) at 298K; and the as represent the activities of the components in orthopyroxene and garnet.

The aim of our experimental approach is to extract values of $\Delta H^\circ_{1,T}$ and ΔS°_T from compositional data obtained over a $P–T–X$ (composition) range. To do this we require an expression or value for ΔV°, and a knowledge or model of the activity–composition relatioships of the phases involved. While we recognize that full, explicit, thermodynamic models of the garnet and orthopyroxene solid solutions are desirable, and that site distribution data exist for orthopyroxene in some chemical systems[18,19], the nature of the data obtainable from

* Garnet–clinopyroxene thermometer[64]. † Garnet–orthopyroxene thermometer[65]. ‡ Two-pyroxene thermometer[34]. § Phase petrology constraints.

the experiments presented here precludes the use of complicated multi-parameter solution models. A simpler approach which allows direct application to natural rock data has been pursued. Simple solution models applicable in the MAS and CMAS systems have been adopted, and essentially empirical curve-fitting parameters which describe the compositional dependences of Al-solubility in orthopyroxene in the Fe-bearing systems have been added. By taking the solid solution properties of the phases into account, the empirical terms have a similar form to terms describing non-ideal solid solution behaviour in more rigorous formulations.

In the MAS system, the activity of garnet is unity. Using the two-site model of Wood[5] for orthopyroxene, and assuming that no Al enters the M2 site:

$$a^{\mathrm{op}}_{\mathrm{En}}a^{\mathrm{op}}_{\mathrm{MgTs}} = X^{\mathrm{M1}}_{\mathrm{Al}}(1-X^{\mathrm{M1}}_{\mathrm{Al}})\gamma^{\mathrm{M1}}_{\mathrm{Mg}}\gamma^{\mathrm{M1}}_{\mathrm{Al}}$$

Recent work indicates that some Al may enter the M2 site[19], however, the simpler model above is adopted to allow development of a practical geobarometer.

Following Wood and Banno[20], Mg–Al orthopyroxenes have been assumed to mix ideally at 1 bar, and non-ideal interactions at higher pressure have been arbitrarily ascribed to an excess volume of mixing term ΔV_{ex}. Substitution of this term, derived from available molar volume data[14,21], for the standard molar volume change of reaction (ΔV°), results in a *P–T*-dependent volume change of reaction, ΔV_{r}:

$$\Delta V_{\mathrm{r}} = -[183.3+178.98(X^{\mathrm{M1}}_{\mathrm{Al}}(1-X^{\mathrm{M1}}_{\mathrm{Al}}))] \quad \mathrm{cal\ kbar^{-1}} \qquad (3)$$

Thus, in MAS:

$$\Delta G^{\circ}_{1,\mathrm{T}} = RT\ln[X^{\mathrm{M1}}_{\mathrm{Al}}(1-X^{\mathrm{M1}}_{\mathrm{Al}})]-P\Delta V_{\mathrm{r}}$$

With the addition of Fe into the system, both garnet and orthopyroxene vary in composition with *P* and *T*. In orthopyroxene several effects will arise from non-ideal interactions occurring on either 'M1' or 'M2' site or across sites (reciprocal terms). While recognizing these complexities and that garnet is no longer a pure component, the effects of adding Fe to the MAS system have been ascribed to one, empirical, curve-fitting term which accounts for the variation of Al-solubility in orthopyroxene with $X^{\mathrm{op}}_{\mathrm{Fe}}$ at one *P–T* condition (Fig. 1). This excess term is dominated by non-ideal Fe–Al interactions in the M1 site of orthopyroxene and is of the form:

$$\Delta H_{\mathrm{ex}} = W^{\mathrm{M1}}_{\mathrm{FeAl}}(1-X^{\mathrm{M1}}_{\mathrm{Al}})(1-2X^{\mathrm{M1}}_{\mathrm{Al}})X^{\mathrm{op}}_{\mathrm{Fe}}$$

with

$$X^{\mathrm{op}}_{\mathrm{Fe}} = \mathrm{Fe/Mg+Fe\ in\ orthopyroxene\ and}$$

$$X^{\mathrm{M1}}_{\mathrm{Al}} = \mathrm{Al/2\ in\ 6\ oxygen\ unit\ orthopyroxene}$$

Note that the $W^{\mathrm{M1}}_{\mathrm{FeAl}}$ parameter derived here is an empirical term only, and its magnitude is the net result of a number of effects in the orthopyroxene solid solution. Nevertheless, the ΔH_{ex} term adequately describes the deviation of Al-contents of Fe–Mg orthopyroxenes coexisting with garnet from those of an Mg-orthopyroxene at the same *P–T* condition.

In the CFMAS system, further terms must be introduced to account for the decrease in alumina contents of orthopyroxenes

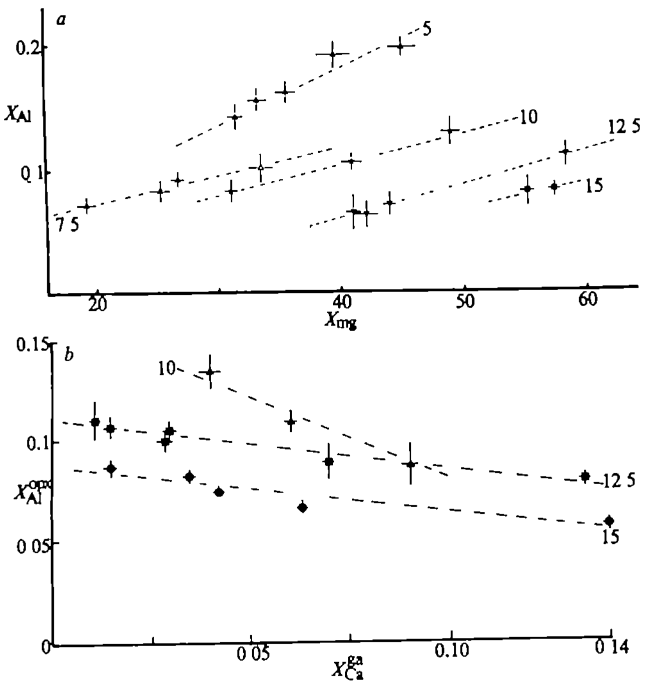

Fig. 1 *a*, Example of an experimental data set in the FMAS system showing the dependence of Al ($X_{\mathrm{Al}} = \mathrm{Al}/2$) solubility in orthopyroxene on Fe–Mg substitution in the pyroxene at 1,248K. Dashed lines join isobaric data, with pressures as indicated. Similar data has been obtained at 1,173K, 1,323K and 1,423K. $X_{\mathrm{Mg}} = (\mathrm{Mg}/\mathrm{Mg}+\mathrm{Fe}) \times 100$ in orthopyroxene. Error bars, one standard deviation (1σ) based on 10–15 orthopyroxene analyses. *b*, Example of an experimental data set in the CFMAS system showing the dependence of Al-solubility in orthopyroxene on the grossular content of coexisting garnet, at near-constant $X_{\mathrm{Mg}}(X_{\mathrm{Mg}}^{\mathrm{op}} = 60)$ and at 1,248K. Dashed lines join isobaric data, with pressures as indicated. Similar data has been obtained at 1,323K. $X_{\mathrm{Ca}}^{\mathrm{ga}} = (\mathrm{Ca}/\mathrm{Ca}+\mathrm{Mg}+\mathrm{Fe})$ in garnet.

with increasing Ca-contents of coexisting garnet. In comparison with the FMAS equation used above, where $X_{\mathrm{py}}^{\mathrm{ga}}$ is left as unity, in CFMAS the equation is adjusted using two terms:

(1) A dilution term incorporated into the expression for ln *K*

$$X_{\mathrm{py}}^{\mathrm{ga}\;3} = (1 - X_{\mathrm{Ca}}^{\mathrm{ga}})^3$$

(2) An additional term derived from a ternary regular-symmetric solid solution model for Ca–Mg–Fe garnets, with the constraints obtained from other phase equilibrium experiments that Ca–Fe and Fe–Mg interactions in garnet are near-ideal in the *P–T* range of interest[22–24]:

$$RT \ln \gamma_{\mathrm{py}}^{\mathrm{ga}} = W_{\mathrm{CaMg}}^{\mathrm{ga}} [X_{\mathrm{Ca}}^{\mathrm{ga}} X_{\mathrm{Fe}}^{\mathrm{ga}} + (X_{\mathrm{Ca}}^{\mathrm{ga}})^2]$$

where

$$X_{\mathrm{Ca}}^{\mathrm{ga}} = \mathrm{Ca}/\mathrm{Ca}+\mathrm{Mg}+\mathrm{Fe}, \text{ and } X_{\mathrm{Fe}}^{\mathrm{ga}} = \mathrm{Fe}/\mathrm{Ca}+\mathrm{Mg}+\mathrm{Fe}.$$

Note that this second term results in a derived $W_{\mathrm{CaMg}}^{\mathrm{ga}}$ which is a curve-fitting parameter only, as the term $(1 - X_{\mathrm{Ca}}^{\mathrm{ga}})$ rather than $X_{\mathrm{Mg}}^{\mathrm{ga}}$ has been used for the mole fraction of garnet. Even though the derived $W_{\mathrm{CaMg}}^{\mathrm{ga}}$ is an empirical parameter, the equations used here should give the correct form of Ca–Mg interaction in garnet.

Thus, in CFMAS an equation is derived which expresses the alumina content of orthopyroxene coexisting with garnet as a function of *P*, *T*, $X_{\mathrm{Fe}}^{\mathrm{op}}$, $X_{\mathrm{Ca}}^{\mathrm{ga}}$ and $X_{\mathrm{Fe}}^{\mathrm{ga}}$:

$$\begin{aligned} \Delta G^{\circ}_{1,T} = {} & RT \ln [X_{\mathrm{Al}}^{\mathrm{M1}} (1 - X_{\mathrm{Al}}^{\mathrm{M1}})/(1 - X_{\mathrm{Ca}}^{\mathrm{ga}})^3] - P\Delta V_{\mathrm{r}} \\ & + W_{\mathrm{FeAl}}^{\mathrm{M1}} (1 - X_{\mathrm{Al}}^{\mathrm{M1}})(1 - 2X_{\mathrm{Al}}^{\mathrm{M1}}) X_{\mathrm{Fe}}^{\mathrm{op}} \\ & + 3 W_{\mathrm{CaMg}}^{\mathrm{ga}} [X_{\mathrm{Ca}}^{\mathrm{ga}} X_{\mathrm{Fe}}^{\mathrm{ga}} + (X_{\mathrm{Ca}}^{\mathrm{ga}})^2] \end{aligned} \quad (4)$$

The development of this equation has essentially relied on the application of compositional correction factors, derived from either the orthopyroxene (in FMAS) or the garnet (in CFMAS) solid solutions, to a simple equilibrium relation applicable in MAS, and thus the derived parameters are partly empirical and may incorporate a greater number of more subtle effects in the solid solutions considered.

Experimental data on garnet–orthopyroxene equilibria

Equation (4) may be used in the reduction of experimental data obtained over a range of P–T–X_{Mg}(bulk)–X_{Ca}(bulk) conditions, given that values of $X_{\mathrm{Al}}^{\mathrm{M1}}$, $X_{\mathrm{Mg}}^{\mathrm{op}}$, $X_{\mathrm{Ca}}^{\mathrm{ga}}$ and $X_{\mathrm{Fe}}^{\mathrm{ga}}$ can be obtained experimentally. In this experimental study, two sets of experiments designed to obtain data sets for these compositional parameters have been undertaken:

(1) Experiments in the system FMAS at a range of X_{Mg}(bulk) values (=0.15, 0.30, 0.45, 0.50, 0.60, 0.70, 1.0), with bulk compositions appropriate to form garnet–orthopyroxene–quartz at a given *P–T* condition. These have been performed with both almandine and Al-free enstatite mineral mixes (X_{Mg}(bulk) = 0.33), and glass mixes seeded with 5% almandine or pyrope to promote garnet growth. It is considered that mineral-mix type starting materials constitute reversal mixes to glass starting materials, an assumption confirmed by analyses of orthopyroxenes grown from glass ($X_{\mathrm{Al}}^{\mathrm{M1}}$ decreases rimwards) and from enstatite seeds ($X_{\mathrm{Al}}^{\mathrm{M1}}$ increases rimwards).

(2) Experiments in CFMAS at X_{Mg}(bulk) = 0.50 and over a range of X_{Ca}(bulk) values (= 0.02, 0.04, 0.08) so as to produce garnets of differing $X_{\mathrm{Ca}}^{\mathrm{ga}}$ at essentially one P–T–$X_{\mathrm{Mg}}^{\mathrm{op}}$ condition. In these experiments, glass starting materials with 5% almandine seeds have been used exclusively, and the effect of $X_{\mathrm{Ca}}^{\mathrm{ga}}$ on $X_{\mathrm{Al}}^{\mathrm{M1}}$ has been evaluated by comparison of compositional data in this set of experiments with data previously obtained and reversed in FMAS.

All experiments have been performed in a Boyd-type, 1/2-inch, solid–medium, piston–cylinder apparatus. Temperatures were monitored by Pt/Pt90Rh10 thermocouples to within ± 10 °C of the set point during the prolonged run durations involved in ensuring subsolidus equilibration (4 days to 1 month, depending on the temperature). Pressures, monitored by Heise gauge, are believed to be accurate to within 0.5 kbar. All runs were of piston-in type, and a −10% friction correction has been applied to all nominal gauge pressures as talc outer sleeves were used. All samples were loaded into 3- or 4-bore Fe-metal or graphite capsules which were then sealed in noble metal outer capsules. Thus three or four mixes of differing bulk composition could be simultaneously run at one *P–T* condition.

Examples of the effects of $X_{\mathrm{Mg}}^{\mathrm{op}}$ and $X_{\mathrm{Ca}}^{\mathrm{ga}}$ on $X_{\mathrm{Al}}^{\mathrm{M1}}$, at various pressures for a given temperature, are illustrated in Fig. 1. The

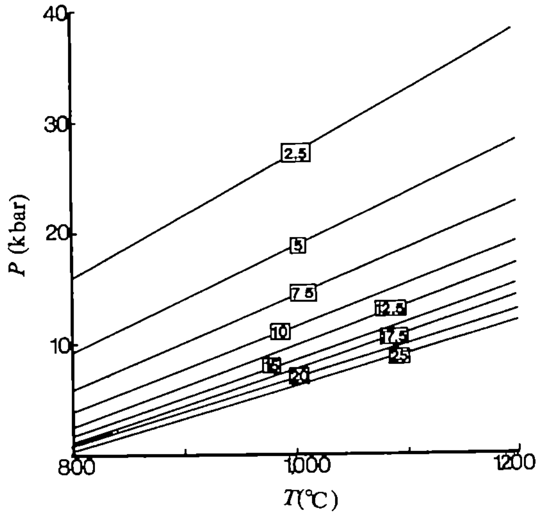

Fig. 2 X_{Al} (Al/2) isopleths for hypothetical orthopyroxene with $X_{\mathrm{Mg}}^{\mathrm{op}} = 50$, in equilibrium with Fe–Mg garnet. Isopleths are expressed as % Al in the M1 site.

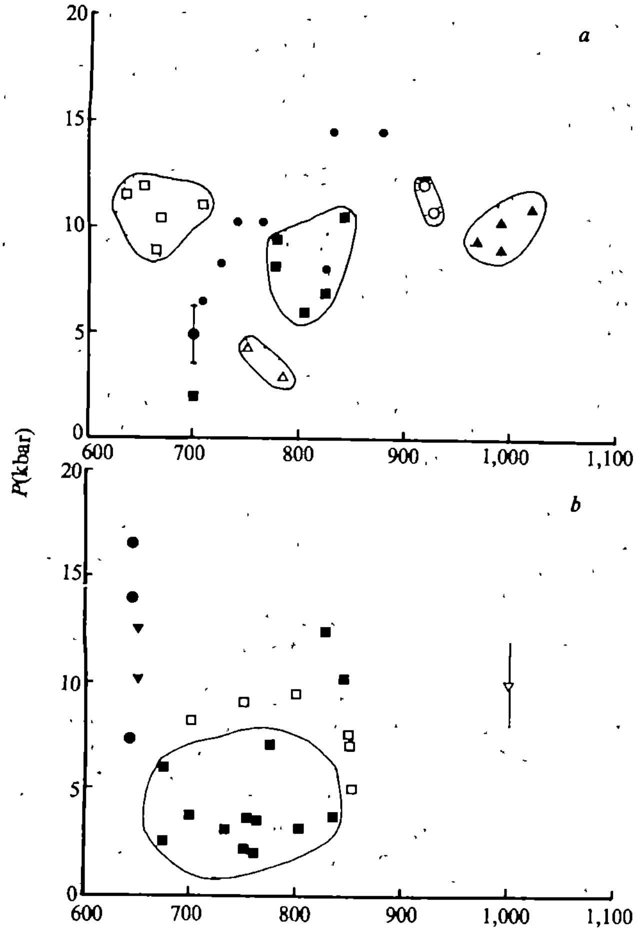

Fig. 3 P–T estimates for published examples of garnet–orthopyroxene-bearing granulites. P estimated from equation (5), T estimates as indicated in Table 1. *a*: □, Greenland[47]; ■, Scourie[6]; ○, Aldan Shield[32]; ▲ Kola Peninsula[30]; △, West Australia[50]; ●, Vredefort,[51]; •, Greenland and Scotland[48,49]. *b*, ■ Nain, Labrador,[38,39]; ▼, Norway[52]; ●, Adirondacks[53]; □, India[54–56]; ▽, Uganda[33].

principal effects to be noted are:

X^{M1}_{Al} decreases with increasing P at constant T, X^{op}_{Mg} and X^{ga}_{Ca}

X^{M1}_{Al} increases with increasing T at constant P, X^{op}_{Mg} and X^{ga}_{Ca}

X^{M1}_{Al} increases with increasing X^{op}_{Mg} at constant P, T and X^{ga}_{Ca}

X^{M1}_{Al} decreases with increasing X^{ga}_{Ca} at constant P, T and X^{op}_{Mg}

The experimental data in FMAS, a total of 75 data points, have been fitted to equation (4), with $X^{ga}_{Ca} = 0.0$, yielding best-fit multiple and stepwise regression parameters as follows:

$$\Delta H^{\circ}_{1,T} = -5{,}650 \pm (250)\ \text{cal mol}^{-1}$$

$$\Delta S^{\circ}_{T} = -2.93 \pm (0.30)\ \text{cal mol}^{-1}\ \text{K}^{-1}$$

$$W^{M1}_{FeAl} = 5{,}157 \pm (200)\ \text{cal mol}^{-1}$$

(figures in brackets are standard errors at the 1σ level).

Compositional data in CFMAS at $X^{op}_{Mg} = 0.60$ have then been fitted to equation (4) using the parameter values above, to obtain a least-square fit value of W^{ga}_{CaMg}

$$W^{ga}_{CaMg} = 2{,}100 \pm (200)\ \text{cal mol}^{-1}$$

Correction of equation (4) for excess molar volume terms in CaMg garnet[25], leads to a value of 2,530±200 cal mol^{-1} for this empirical parameter, in reasonable accord with values of W^{ga}_{CaMg} obtained in other studies[24,26,27].

Equation (4) may now be rearranged into an equation expressing P (kbar) in terms of T, X^{op}_{Mg}, X^{M1}_{Al}, X^{ga}_{Ca} and X^{ga}_{Fe}. This equation is useful as a geobarometer in granulite facies garnet–orthopyroxene assemblages and in garnet periodotites:

$$\begin{aligned} P\ (\text{kbar}) &= \frac{1}{\Delta V_r}[(R \ln K - 2.93)T + 5{,}650 \\ (\pm 1\ \text{kbar}) &\quad + 5{,}157(1 - X^{M1}_{Al})(1 - 2X^{M1}_{Al})X^{op}_{Fe} \\ &\quad - 6{,}300[X^{ga}_{Ca}X^{ga}_{Fe} + (X^{ga}_{Ca})^2] \end{aligned} \qquad (5)$$

where T is in (Kelvin; $K = [X^{M1}_{Al}(1 - X^{M1}_{Al})/(1 - X^{ga}_{Ca})^3]$; $\Delta V_r = -[183.3 + 178.98(X^{M1}_{Al}(1 - X^{M1}_{Al}))]$ cal kbar^{-1}.

The geobarometer will be limited by the following circumstances: (1) where Fe^{3+} contents are high in garnet or orthopyroxene, such that other non-ideal terms may be important in the garnet, or the $Fe^{3+}AlMg_{-1}Si_{-1}$ exchange may be important in orthopyroxene[28,29]; (2) where Cr^{3+} contents are high in garnet; (3) where Mn^{2+} contents are high in the phases.

In addition, the barometer will be subject to considerable uncertainty when either (1) Al_2O_3 contents in orthopyroxene are very low (such as high pressure garnet peridotites, or high Fe–Ca garnet assemblages formed at low temperatures), or (2) there are large uncertainties in the temperature estimate, as the dP/dT slopes of the Al_2O_3 isopleths are approximately 4 kbar per 100 °C (Fig. 2).

Applications of garnet–orthopyroxene geobarometry

The garnet–orthopyroxene geobarometer developed here (equation (5)) has been applied to several well-documented examples of granulite facies metamorphics, and to low-Cr garnet peridotite xenoliths in kimberlites from South Africa. The results of these calculations are presented in Fig. 3 and Table 1, together with the P–T conditions suggested by other workers for these samples on the basis of other geothermobarometric techniques or phase stability constraints.

Sillimanite- or sapphirine-bearing garnet–orthopyroxene assemblages reported from the USSR[30–32] and Uganda[33] yield P estimates which are consistent with the stability of sillimanite and with the stability of the assemblage orthopyroxene–sillimanite–quartz at 1,000 °C (ref. 34). Granulites from Enderby Land, Antarctica[35], yield pressures of 7–9 kbar, consistent with the stability of sillimanite in interlayered metapelites and with phase assemblages in associated aluminous granulites[36].

Retrograde garnet-bearing coronas in meta-igneous granulites from several areas (Table 1) yield pressure estimates in the range 7–12 kbar, which is consistent with the reported incoming of kyanite in metapelites associated with these coronites in some areas[37]. Unrealistic or highly uncertain P estimates are obtained, however, for some of these corona textures (for example, Adirondacks, Scourie). This may result from inadequacies in the experimental calibration at extreme Ca- and Fe-rich compositions, from the large errors inherent in the barometry at low X^{M1}_{Al} values, or from failure to obtain adjacent analyses of minerals in local equilibrium in otherwise zoned coronas. The Nain[38], Labrador, granulites, which occur in a thermal aureole around an anorthosite pluton, yield an average pressure estimate consistent with pressures of 3.2 kbar recently obtained for these rocks from olivine–orthopyroxene–quartz equilibria[39,40].

Granulitic and websteritic nodules from diatremes in southeastern Australia and the USA[41–44] yield pressures of 12.5–16 kbar, which are in good agreement with pressures inferred by Irving[42] for the equilibration of scapolite granulites from Delegate, New South Wales. Spinel–garnet lherzolite xenoliths from southeastern Australia[45], estimated to have equilibrated at 25 kbar by O'Neill[46] using the spinel to garnet peridotite transition as a barometer, yield pressures of 22–24 kbar using equation (5).

Comparison with most alternative pressure estimates considered here indicates that the experimentally derived geobarometer presented in equation (5) can be used successfully to estimate the pressures of formation and equilibration of garnet–orthopyroxene assemblages, provided a reliable temperature estimate can be obtained from other equilibria. Calculated pressures will, however, be heavily dependent on the deduced temperature. As in all geothermometry/geobarometry using several equilibria, it is also necessary to assume that closure temperatures are the same for the equilibria used.

We thank D. J. Ellis and C. Hatton for useful comments and K. L. Harris for his aid with the piston–cylinder apparatus. This work formed part of S. H.'s PhD. research project at the University of Tasmania, and was supported by a Commonwealth of Australian Postgraduate Research Scholarship to S. H. and an ARGC grant to D.H.G.

Relaxation of muscle fibres by photolysis of caged ATP

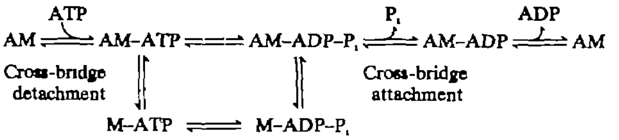
A novel method has been developed for studying the reaction kinetics of the force-generating mechanism in muscle. Inert photolabile precursors of ATP or ADP are incorporated into muscle fibres having their surface membrane barrier removed. The nucleotide is then rapidly liberated by laser pulse photolysis. This circumvents the limitation in time resolution set by diffusion of nucleotide from the medium bathing the fibre. This laser photolysis method may be applicable to studies of the dynamic properties of many biological systems.

THE energy transducing mechanism of muscle is widely thought to involve a cyclic reaction of cross-bridges between thick and thin filaments[1,2]. Lymn and Taylor proposed a scheme relating the chemistry of the actomyosin ATPase to muscle contraction[3]. This scheme, expanded to include some recently characterized steps is[4–6]:



(1)

Kinetic studies using the isolated proteins indicate that ATP binds to the AM state (actomyosin with no bound nucleotide) and induces rapid detachment of the myosin head from actin[7]. We have used a laser photolysis method to study the corresponding reaction in muscle fibres capable of contracting. Muscle fibre tension and high frequency stiffness were monitored after rapid increases in ATP concentration to determine the kinetics of the mechanical events that follow binding of nucleotide to the cross-bridges.

Although solution experiments have demonstrated the reversibility of the actin–myosin association and dissociation reactions, and direct ATP hydrolysis without dissociation (shown above as dashed arrows)[8,9], for clarity of the experimental description, treatment of these phenomena is deferred to the discussion.

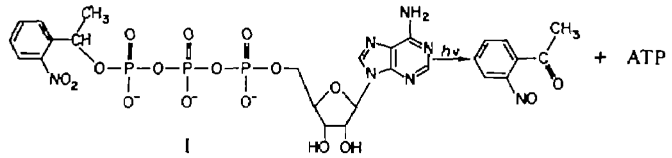
Photochemical initiation of cross-bridge detachment

The tension record of Fig. 1 illustrates the experimental procedure. A skinned single fibre from rabbit skeletal muscle was initially relaxed (solution 1). Transfer to a medium without ATP (solution 2) resulted in tension development as cross-bridges accumulated in the rigor (AM) state. The inert precursor of ATP, P^3-1-(2-nitro)phenylethyladenosine 5'-triphosphate, I, termed caged ATP[10], was added to the bathing medium (solution 3) and allowed to diffuse into the fibre. This caused little alteration of the rigor tension. At the arrowhead of Fig. 1 a pulse of UV radiation ($\lambda = 347$ nm) from a frequency-doubled ruby laser initiated the photolysis reaction[11]:



In the experiment shown in Fig. 1, 750 μM ATP was liberated in the muscle chamber. The rate of ATP release, set by photochemical dark reactions[11], was 100 s^{-1} in the solutions used in this study. Production of ATP in the presence of excess Mg^{2+} ions but no added Ca^{2+} resulted in a rapid decrease of tension to the relaxed level. Figure 1*b* shows the same tension decay on a faster time base. The arrowhead indicates the laser pulse. After a brief delay, partly due to the photochemical reaction, tension decreased with a half time ($t_{1/2}$) of ~5 ms. Thus ATP detaches cross-bridges rapidly in muscle fibres.

To make a kinetic comparison of cross-bridge detachment with the rate of actomyosin dissociation in solution, the amount of ATP liberated was varied by altering the intensity of the light pulse. Figure 2*a*–*c* shows transients of relaxation from rigor for several ATP concentrations. The upper traces in each panel are records of the high-frequency mechanical stiffness of the fibres, which is a qualitative indication of the number of cross-bridge attachments[12]. After the light pulses (arrows), the stiffness decayed, indicating cross-bridge detachment. Accompanying the stiffness decrease there was a delayed rise in force and then a decrease to the relaxed level (lower traces). As the ATP concentration was reduced, the peak in tension was delayed, the amplitude of the tension rise increased and the final relaxation was slower.

The time taken for the force to decay from the peak of the tension rise to half that value was converted to an apparent rate constant using the relation $k_{obs} = (\ln 2)/t_{1/2}$. This method of analysis ignores deviations of the final tension decay from a single exponential but is useful for comparison with the analogous experiment on actomyosin in solution. The rate of the final relaxation increased as the ATP concentration increased (see Fig. 2*d*). The slope of this relation, *K*, is a second-order rate constant for the overall detachment process of rigor cross-bridges induced by ATP. The average value for five fibres was $K = 1.9 \pm 0.6 \times 10^5\ M^{-1}\ s^{-1}$ (mean±s.d.) at 20 °C.

When acto-heavy meromyosin or actomyosin subfragment-1 is mixed in solution with ATP in a rapid reaction apparatus, and the dissociation of the myosin heads is monitored by decrease in light scattering, the apparent second-order rate constant for dissociation is $\sim 10^6\ M^{-1}\ s^{-1}$ (ref. 13, using acto-heavy meromyosin at ionic strength = 100 mM, $T = 20$ °C). Thus, our data indicate that in a fibre the rate of cross-bridge detachment from the rigor state is within an order of magnitude of the rate of the corresponding reaction with solubilized proteins.

The sensitivity of the detachment reaction to stress was tested by varying the length of the muscle fibre in rigor before photolysis. Figure 3 shows superimposed tracings of records obtained when small length steps were applied 1 second before the laser pulse. This altered the distribution of forces in the attached cross-bridges, which is apparent in the alteration of the shape of the initial 20 ms of the force transient. For Fig. 3*a*, the muscle fibre was stretched ~30 μm (0.86% of the initial length) before the laser pulse. Photolysis resulted in an initial rapid decrease in tension. The force imposed by the stretch was similar to the force reached during an isometric contraction of these glycerinated muscle fibres. No length change was applied for Fig. 3*b*. Figure 3*c*, *d* was recorded after the length was allowed to decrease. After the laser pulse, tension remained constant or increased before the final relaxation. Although the initial phase of these transients varies greatly in shape, the final phases superimpose.

Initial increase in tension

An initial tension rise was generally apparent if the tension was low (<50 mN mm^{-2}) at the time of the laser pulse. This low rigor tension level could be achieved either by decreasing the length of the muscle fibre just before the laser was triggered (for example, Fig. 3*d*) or by initially inducing rigor in a medium free of divalent metal ions and containing EDTA[14]. The initial rise in tension after liberation of ATP inside the myofibrils was

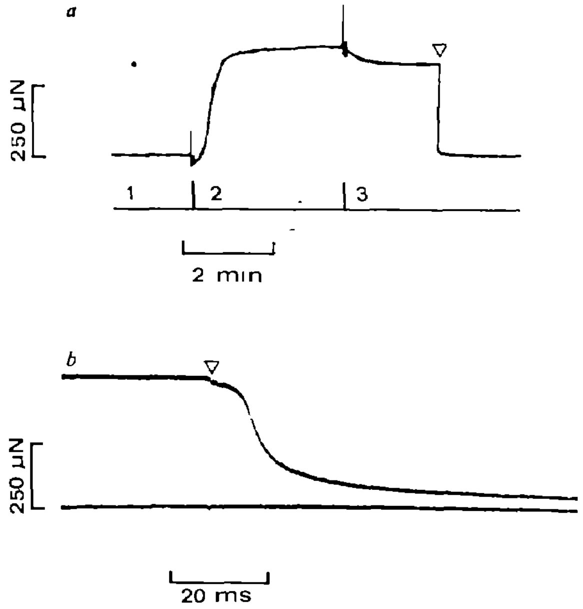


Fig. 1 Tension transient recorded from a single glycerol-extracted rabbit psoas muscle fibre. *a*, The slow time base tension record illustrates the experimental protocol. The fibre (cross-sectional area $7.95 \times 10^{-9}\ m^2$, sarcomere length 2.3 μm) was attached with aluminium clips between a force transducer (natural frequency, 7.5 kHz) and a piezoelectric stack which was used to alter muscle length. The fibre was immersed in a small trough, ~0.5 mm from a quartz window. Bars on the record indicate the timing of the solution exchanges. (1) Relaxing solution containing (in mM): MgATP, 0.1; Mg^{2+}, 1; K^+, 95; EGTA, 30; creatine phosphate (CP), 22; creatine kinase (CK), 1 mg ml^{-1}; TES (*N*-tris[hydroxymethyl] methyl-2-aminoethanesulphonic acid) buffer, 100; reduced glutathione, 10; ionic strength, 200; *p*H 7.1; 21 °C). (2) Rigor solution—same as (1) but without ATP, CP or CK. (3) Photolysis solution—same as (1), but without ATP and including 10 mM caged ATP. Photolysis of caged ATP was initiated at the arrowhead by a 150-mJ, 50-ns pulse of 347 nm light generated by frequency-doubling the output of a 694 nm ruby laser with a temperature-tuned rubidium dihydrogen arsenate crystal. After the rapid relaxation induced by the release of ATP, the photolysis solution was saved and later assayed for ATP using luciferin-luciferase[35,36]. *b*, Fast time base recording of the tension transient illustrated in *a*. The arrowhead indicates the time of the laser pulse. The lower trace is a baseline tension recorded after relaxation in the photolysis solution.

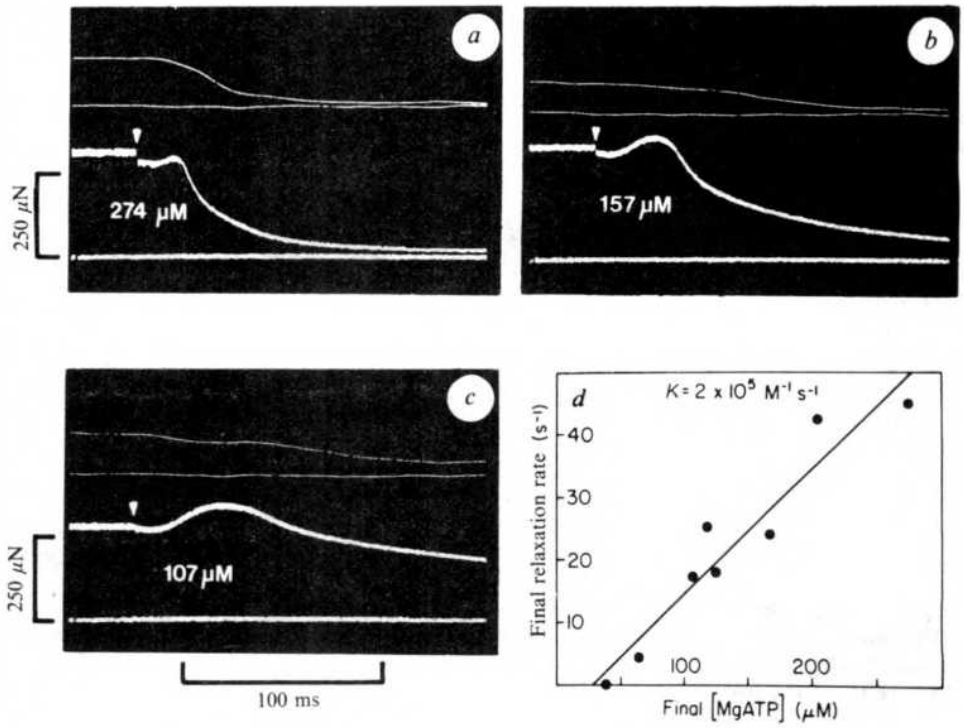

Fig. 2 Time course of relaxation at various concentrations of ATP. *a–c*, Paired stiffness (upper) and tension (lower) records. Lower traces of each pair show the baseline level in the relaxing solution. The degree of photolysis of the initial 2 mM caged ATP was controlled by varying the intensity of the light pulse[11]. Final ATP concentrations are shown for each panel. Stiffness was recorded by altering fibre length sinusoidally at 2.5 kHz and 1 μm amplitude with the piezoelectric stack. The sinusoidal component of the tension recorded in phase with the length change was separated from the d.c. component of tension by a synchronous demodulator. Nonlinear end compliance and sinusoidal phase shift due to stress relaxation may introduce small artefacts into the stiffness records. *d*, Observed rate of final relaxation of tension determined from the $t_{1/2}$ as described in the text. The data are from a single fibre. The line was fitted by linear regression, slope 2×10^5 M^{-1} s^{-1}. The non-zero intercept of the line is probably a reflection of the relatively high concentration of myosin heads within the fibre.

unexpected as mixing MgATP with actomyosin in solution causes rapid dissociation of the myosin head from actin filaments[3,7,13].

Figure 4*a* shows a control experiment with caged ADP that was performed to determine whether the shape of the photolysis-induced mechanical transient was caused by an artefact of the method. The photochemical species and accompanying reactions were identical with those in a caged ATP experiment except that 240 μM ADP was released. Little alteration in tension or stiffness occurred. However, when the liberated ADP was enzymatically converted to ATP by including creatine phosphate (CP) and creatine kinase (CK) in the medium, a tension rise and relaxation were observed (Fig. 4*b*). This indicates that these phenomena were caused solely by the appearance of ATP in the filament lattice.

A possible explanation of the initial increase in tension before relaxation that cross-bridges transiently reattach to the thin filaments shortly after detachment. If the reattached links produce more tension than the detaching cross-bridges, then tension increases. The stiffness (upper traces in Fig. 2*a–c* and Fig. 4*b*) declines during the initial tension rise, which indicates that the combination of detachment and reattachment results in a net detachment throughout the transient.

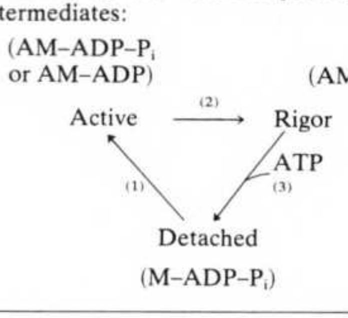
A rapid reattachment of detached cross-bridges might be allowed even in the absence of Ca^{2+} ions by a cooperative effect among thin filament attachment sites which has been demonstrated in other studies[15-17]. The dependence of the ATPase activity of rabbit myosin and regulated thin filaments (actin combined with troponin and tropomyosin) on ATP concentration and the relationship between the steady tension of skinned muscle fibres and ATP concentration are both bell-shaped with maxima at substrate concentrations of 2–30 μM[15-19]. These data can be explained on the basis of a cooperative interaction between thin filament attachment sites such that, if a proportion of cross-bridges are attached in rigor (nucleotide-free) bonds, then the remainder of sites are available for cross-bridge attachment irrespective of Ca^{2+} binding to troponin[15,16]. This cooperativity is consistent with the structure of the thin filaments, since tropomyosin regulates several actin monomers[20]. Interactions between the two heads of the myosin molecule might also account for cooperative attachment.

If cooperativity is to account for the tension rise, cross-bridges must be capable of detaching, reattaching and producing force within the 20–30-ms period between the illumination and the peak of the tension rise (Figs 2*a–c* and 3). The rate of reattachment and force generation can be tested by including Ca^{2+} ions in the photolysis medium, as liberation of ATP in the presence of Ca^{2+} will activate the muscle fibre to contract. If reattachment of cross-bridges occurs slowly compared with the detachment in this condition, then the muscle fibre should relax fully before the active high tension state is reached.

In Fig. 5 the tension record labelled $-Ca^{2+}$ shows a relaxation from rigor initiated by photolysis of caged ATP in the absence of Ca^{2+}. The length of the muscle fibre was allowed to decrease by 1% 1 s before the photolysis and a moderate concentration (190 μm) of ATP was generated in the fibre so that a significant tension rise would occur. In the next trial the fibre in rigor was bathed in a solution containing caged ATP and ~30 μM free Ca^{2+}. Addition of Ca^{2+} ions had little effect on the rigor tension or stiffness. When ATP was released in the presence of Ca^{2+}, the tension rose towards the level of an active contraction. The two force traces diverge within 20 ms after the laser pulse, indicating that the cross-bridges can generate additional force above the rigor level within 20 ms of ATP release. Assuming that rigor cross-bridges detach during this period, the results suggest that reattachment and force generation also occur rapidly.

Kinetic model

The possibility that a rapid reattachment of detached cross-bridges could account for the shape of the force transients was tested by using a restrictive model involving a minimum number of steps. Three cross-bridge states were considered in this calculation: detached, rigor and active. These are shown in the following scheme together with the probable corresponding chemical intermediates:



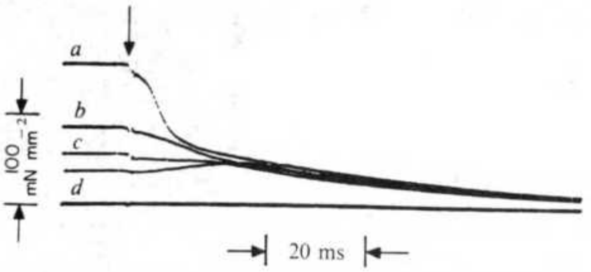


Fig. 3 Superimposed records of relaxation transients produced by photoliberation of ~480 μm ATP. The muscle length (3.5 mm; sarcomere length 2.32 μm) was changed slightly 1 s before the laser pulse. Length steps for each trace were: *a*, 30 μm stretch; *b*, no length step; *c*, 15 μm release; *d*, 30 μm release. Other conditions were as described in Fig. 1 legend. Units of tension per cross-sectional area are given for the force calibration to facilitate comparison with active contractions of glycerinated muscle fibres. The vertical positions of the records were adjusted to superimpose the four baselines (lower trace) showing the relaxed tension.

To introduce cooperativity into the model, the cross-bridge attachment sites were considered in pairs. For each member of a pair, reaction (1), the cross-bridge attachment step, was made to depend on the state of the other attachment. If one site of a pair was attached, then the attachment reaction at the other site was allowed (see Fig. 6 legend). For simplicity, the rate constants of these reactions were made independent of cross-bridge stress and strain. The resulting differential equations were integrated. The attached cross-bridge states were assigned values of force, given in Fig. 6 legend. The concentrations of the states, weighted by these relative forces, were summed to produce simulated curves of the tension time courses.

To simulate the experiments in which a stretch or release was applied to the muscle before the photolysis pulse (Fig. 3), the rigor cross-bridges present at the time of photolysis were given different values of force for each curve in Fig. 6. The shape of the initial portion of the curves depended strongly on the force per rigor cross-bridge. When the initial tension was low, detachment of rigor cross-bridges had a relatively small effect on the calculated tension curve and reattaching cross-bridges generated an increase in force as shown in the experimental records of Fig. 3*d* and 5 ($-Ca^{2+}$). For an intermediate initial tension (Fig. 6*c*), the effects of detaching and reattaching cross-bridges partially cancel, producing a delay similar to the experimental traces of Figs 1*b*, 2*a* and 3*c*. At high starting tensions, a briefer delay before relaxation (simulated trace, Fig. 6*a*; experimental trace, Fig. 3*a*) largely represents the photochemical dark reactions (at $100\ s^{-1}$) between absorption of the UV radiation and ATP release. Reattached cross-bridges were assigned a fixed weight so the later phases of the transients, dominated by reattachments, did not depend on initial rigor tension. This superimposition of the tension traces in the final phases of relaxation is a natural consequence of the reattachment hypothesis and is difficult to reconcile with other possibilities. Although other properties of the filament lattice may contribute to the observed shape of the transients[21], and the cross-bridge cycle in an active contraction may be kinetically very different, this model demonstrates that a cooperative attachment can explain the shape of the mechanical transients initiated by release of ATP within a rigor muscle fibre.

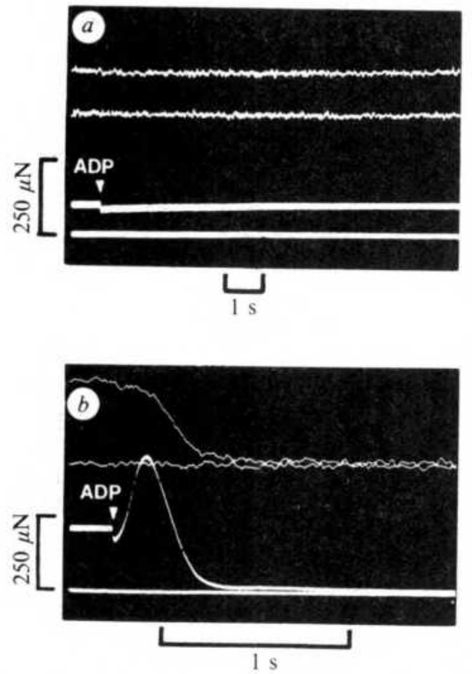

Fig. 4 Tension (lower) and stiffness (upper) records during photolysis of caged ADP. *a*, Caged ADP in the absence of CP and CK. Final ADP concentration was 240 μM. *b*, Photolysis of caged ADP in the presence of CP (22 mM) and CK ($1\ mg\ ml^{-1}$). Final ATP concentration, 290 μM. Conditions and baseline recordings (lower tension and stiffness traces) were as in Fig. 1 except that caged ATP was replaced by 2 mM caged ADP.

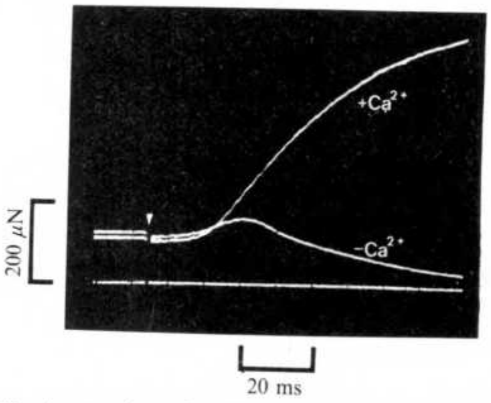

Fig. 5 Tension transients after liberation of 190 μM ATP in the presence ($+Ca^{2+}$) and absence ($-Ca^{2+}$) of free calcium. The muscle fibre (length 3.0 mm, sarcomere length 2.44 μm, cross-sectional area $4.2\times10^{-9}\ m^2$) was released by 30 μm 1 second before the laser pulse. Conditions were as described in Fig. 1 legend except that in the case of the $+Ca^{2+}$ trace, EGTA in the photolysis solution was replaced by 30 mM Ca-EGTA, to give a free Ca^{2+} concentration of ~30 μM.

Discussion

The observed rate of detachment of rigor cross-bridges in our experiments is whithin an order of magnitude of the rate of actomyosin dissociation in solution. This indicates that detachment from the AM state is not greatly slowed by the structural constraints of the filament lattice. The value of the detachment rate constant determined from the rate of the final relaxation over a range of released ATP concentrations ($1.9\times10^5\ M^{-1}\ s^{-1}$) is probably an underestimate of the actual rate as the final decay apparently includes some slow components related to reattaching and cycling cross-bridges. One approach to determining the pure rate of detachment of the rigor cross-bridges is to consider that a mechanical stretch or release of the muscle influences the force production of a particular cross-bridge only until it detaches. In that case, the computed tension difference between two of the traces in the pre-stretch and pre-release experiment (Fig. 3) decays at a rate reflecting the first detachment of the original rigor bonds. The traces converge by 10–30 ms, whereas the final decay of force and stiffness takes longer than 100 ms. This suggests that in muscle fibres the ATP-induced detachment occurs about as rapidly as with the solubilized proteins[3,7,13].

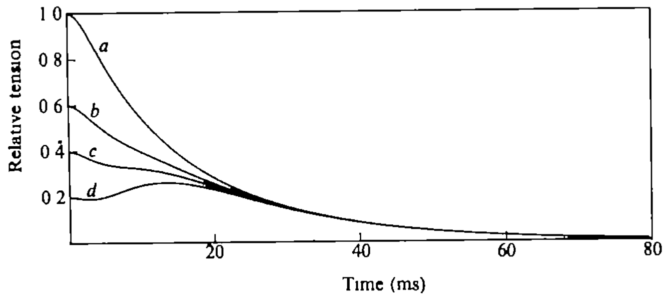

Fig. 6 Simulation of relaxation from rigor, including transient reattachment due to cooperativity between pairs of cross-bridges. Each cross-bridge of a pair was considered to be either in a rigor attachment, an active attachment or detached. Rigor states were further distinguished by whether they had existed continuously from the initiation of the simulation or whether they were formed from reattached active cross-bridges. In either case the second-order rate constant for detachment of a rigor cross-bridge by ATP was taken as $8\times10^5\ M^{-1}\ s^{-1}$. The reattachment rate was $50\ s^{-1}$ for those detached cross-bridges that had an attached partner. If both sites of a pair were detached, then no further attachment was allowed for that pair. The rate constant for transformation of active cross-bridges to rigor-type attachments was $100\ s^{-1}$. No stress- or strain-dependence was considered for any of these rates. Initial rigor cross-bridge concentration was 200 μM. To initiate the reaction, 500 μM ATP was introduced with a first-order rate constant of $100\ s^{-1}$. The resulting set of equations was integrated using the Gear method[37] to calculate how the concentration of each possible combination of pairs of cross-bridges varied with time. The forces generated by undetached rigor, active, and rigor bridges formed from active cross-bridges were given the following relative weights to generate curves of the simulated force transients after photolysis: *a*, 1, 3, 1; *b*, 0.6, 3, 1; *c*, 0.4, 3, 1; *d*, 0.2, 3, 1. Choice of these weights assumes that the state of reattached cross-bridges does not depend on the original rigor tension. Many features of the experimental records are apparent in this simulation.

Our experiments do not provide evidence concerning the extent of the direct hydrolysis pathway (dashed arrows in scheme 1) or the reversibility of the detachment step[8,9]. However, when the strain on a cross-bridge, induced by an applied stretch, is relieved on the first detachment, then the rapid convergence of the tension traces discussed above indicates the rate of the first detachment of the cross-bridges whether or not subsequent reattachment occurs before the hydrolysis step.

Detachment of cross-bridges from the rigor state with a $t_{1/2}$ of less than 10 ms (Fig. 1) is strikingly faster than the steady turnover rate of the actomyosin ATPase in isometric contractions (0.2–$1\ s^{-1}$; refs 19, 22–24). Thus, as a cross-bridge proceeds through the isometric contractile cycle, only a small proportion of time (<1%) is spent in the AM state. If the AM state which is present in rigor muscle fibres is the same as the nucleotide-free intermediate in the normal active cross-bridge cycle, then a cross-bridge which enters the AM state binds ATP and detaches within a few milliseconds.

During active shortening at forces less than the isometric value, the rate of energy liberation is three to five-fold higher than in an isometric contraction[25–27]. This control of energy liberation is not expected to occur at the step of AM dissociation as that reaction is not rate-limiting. This was confirmed by experiments in which stretches and releases were applied to the fibres in rigor before the laser pulse (Fig. 3); there was no decrease of detachment rate when the tension was increased into the range of physiological contractions.

Force transients in single muscle fibres which are initiated by a rapid change in length also indicate that the mechanics of the rigor state are different from the major force-producing states populated in an active contraction[28,29]. When an active muscle undergoes a small step decrease in length, the force drops and then recovers within the next few milliseconds to almost the original tension level[30]. This quick recovery phase may reflect the normal force generation process. The structural correlate of the steps between attachment and force generation might be a rotation or rocking motion of the myosin head towards the Z-line[2,30]. In rigor, force transients initiated by rapid length changes show much less quick tension recovery[28,29]. Thus, the motions or configurations available to the cross-bridge in its force producing state are not all available to the rigor cross-bridge. Several previous studies of rigor cross-bridge orientation, using C-ray scattering[31], fluorescence polarization[32] and electron paramagnetic resonance[33], have indicated that alterations of force caused by applied length changes do not rotate rigor cross-bridges.

Which intermediates would be predominant in a contraction? Our experiments show that cross-bridge detachment is too fast for sites to spend a large proportion of time in the AM (rigor) state. Unless Ca^{2+} markedly slows detachment from rigor, the result in the presence of Ca^{2+} (Fig. 5) indicates that the reactions of the detached cross-bridge and of reattachment are also too rapid to be limiting in an active contraction cycle. These data suggest that the rate limitation occurs between force production by the cross-bridge and rebinding of ATP. During a steady active isometric contraction, most of the cross-bridges would then be attached in the states that generate force. X-ray and mechanical data also support the hypothesis that most cross-bridges are attached during active isometric contractions[28,34]. The structural, mechanical, and kinetic data all suggest a model of the cross-bridge cycle in which the mechanical power transfer and control of energy liberation are separate from the detachment reaction and occur between corss-bridge attachment and the AM rigor intermediate.

We thank Ms J. A. Dantzig and Mrs F. Itshak for technical assistance. The research was supported by NIH research grants HL15835 to the Pennsylvania Muscle Institute and AM00745. M.G.H. was a fellow of the Muscular Dystrophy Association of America.

Functionally homologous cell cycle control genes in budding and fission yeast

David Beach*, Barbara Durkacz & Paul Nurse

School of Biological Sciences, University of Sussex, Brighton, Sussex BN1 9QG, UK

The cdc *2 (previously called* wee *2) cell cycle start gene of* Schizosaccharomyces pombe, *which is required for start and the control of mitosis, has been isolated from an* S. pombe *gene bank by complementation of a* cdc *2 mutation. A functionally homologous sequence which complements the* cdc *2 mutation has also been isolated from a* Saccharomyces cerevisiae *gene bank and this sequence has been shown to contain the* cdc *28 cell cycle start gene of* S. cerevisiae. *It is concluded that the* cdc *2 and* cdc *28 genes perform homologous cell cycle control functions in the two organisms.*

THE fission yeast *Schizosaccharomyces pombe* and the budding yeast *Saccharomyces cerevisiae* have both been used as model organisms for studying the eukaryotic cell cycle[1,2]. This work has made extensive use of temperature-sensitive *cdc* (cell division cycle) mutants which become specifically arrested during the cell cycle when incubated at their restrictive temperatures; over 40 *cdc* genes have been described in *S. cerevisiae* and over 25 in *S. pombe*. All of these are required for normal cell division but only a few are expected to be involved directly in cell cycle controls such as commitment to the mitotic cycle and regulation of the rate of cell division. In *S. cerevisiae*, four genes (*cdc* 28, 36, 37 and 39) have been shown to have roles in a major cell cycle control called 'start'[3-6]. Cells accumulate in G_1 at start in poor nutritional conditions and under the influence of the mating hormones. Mutants of the four *cdc* genes block cell cycle progress at start and are able to conjugate from their point of cell cycle arrest. Once start has been completed the cell becomes committed to the mitotic cycle and is unable to undergo the alternative developmental pathway of conjugation. Completion of start is also the major rate-limiting step of the cell cycle regulating the rate of cell division[3,4]. In *S. pombe* there are two start genes, *cdc* 2 and *cdc* 10 (ref. 7). Mutants of these two genes block in G_1 and are able to conjugate from that point of arrest. In poor nutritional conditions, *S. pombe* cells also accumulate before start. Thus the cell cycles of both organisms can be divided operationally into an uncommitted pre-replicative phase before start and a committed replicative phase consisting of S-phase, mitosis and cell division after start (Fig. 1).

Although start divides the cell cycles of the two yeasts into two similar phases this does not necessarily mean that the two start events have the same molecular basis in the two organisms, especially as they are not closely related. To establish whether the molecular basis of start is indeed similar we have made use of the fact that *cdc* start genes can be physically isolated by complementation and can be transferred from one yeast to the other. From these experiments we establish that *S. cerevisiae cdc* 28 can complement *cdc* 2 mutations of *S. pombe*, suggesting that the start events have a similar molecular basis in the two organisms.

Isolation of the *S. pombe cdc* 2 gene

A sequence containing a *cdc* start gene of *S. cerevisiae* has been selected from a bank of budding yeast DNA by its ability to complement the appropriate *cdc* mutation[8]. The development of techniques for high frequency transformation of *S. pombe* and the construction of a gene bank in a yeast–bacterial shuttle vector[9,10], makes the same approach feasible in *S. pombe*.

A *Hin*dIII partial *S. pombe* gene bank was made in vector pDB262, which contains the *S. cerevisiae leu* 2 gene and can complement the *leu* 1.32 mutation of *S. pombe*[9,10]. The gene bank was used to isolate the *cdc* 2 start gene by transforming a *cdc* 2.33 *leu* 1.32 strain to Leu$^+$ prototrophy and replica-plating the resultant 30,000 clones to 35 °C, at which temperature *cdc* 2.33 cells elongate and die (Fig. 2*b*; ref. 11). Clones that continued to divide at 35 °C were isolated and the plasmids which they contained were recovered in *Escherichia coli*[9,10]. One of these plasmids was found to complement the *cdc* 2.33 and *cdc* 2.M26 mutations when retransformed back into strains containing these mutations. The dividing cells in these transformant clones were elongated (Fig. 2*c*) compared with wild-type dividing cells (Fig. 2*a*), indicating incomplete suppression of the mutant phenotype by the insert on the plasmid. The plasmid was termed pcdc2.3(Sp) and contained a 7-kilobase (kb) insert. A 1.4-kb *Hin*dIII fragment from this insert was recloned into vector pDAM6 which contains the *S. cerevisiae leu* 2 and pBR322 but no sequence capable of supporting replication in *S. pombe*. This plasmid, pcdc2.32(Sp), was transformed into a *S. pombe leu* 1.32h$^-$ strain and some of the Leu$^+$ prototrophic transformants formed were found to be mitotically stable and were presumed to have arisen by plasmid integration into the chromosomal *cdc* 2 gene. This was confirmed for two of the integrants by preparing DNA from cells of the *leu* 1.32h$^-$ strain before integration and after integration of pcdc2.32(Sp). The DNA was digested with *Bam*HI, an enzyme which does not cut within the 1.4-kb *Hin*dIII insert but cuts once in the vector pDAM6 (Fig. 3). After Southern transfer the digested DNAs were probed with ^{32}P-labelled pcdc2.32(Sp) (Fig. 3). The 13-kb *Bam*HI fragment of DNA from cells before integration was altered to two fragments of 17 and 8 kb after integration for both integrants (see Fig. 3 for explanation). This result demonstrates that pcdc2.32 (Sp) integrated at the chromosomal site homologous to the 1.4-kb *Hin*dIII insert. We demonstrated that this site was the *cdc* 2 locus by showing that the Leu 1$^+$ marker phenotype of the plasmid was closely linked to *his* 3, a marker localized within 1 centimorgan of the *cdc* 2 locus[12]. The two pcdc2.32(Sp) integrants in strain *leu* 1.32 h$^-$ were crossed to a *his* 3$^-$ *leu* 1.32 h$^+$ strain. The resultant zygotes were sporulated and the phenotypes of 400 spores of both crosses examined. In both cases less than seven recombinant spores (*leu* 1$^+$ *his* 3$^-$ or *leu* 1$^-$ *his* 3$^+$) were observed, indicating that the *S. cerevisiae leu* 2 gene must have integrated within 1.7 centimorgans of *his* 3. Therefore, pcdc2.3(Sp) contains the *S. pombe cdc* 2 start gene.

Isolation of a *S. cerevisiae* sequence complementing *cdc* 2

Having shown that a sequence containing the *cdc* 2 gene could be isolated from *S. pombe*, we next tried to establish whether

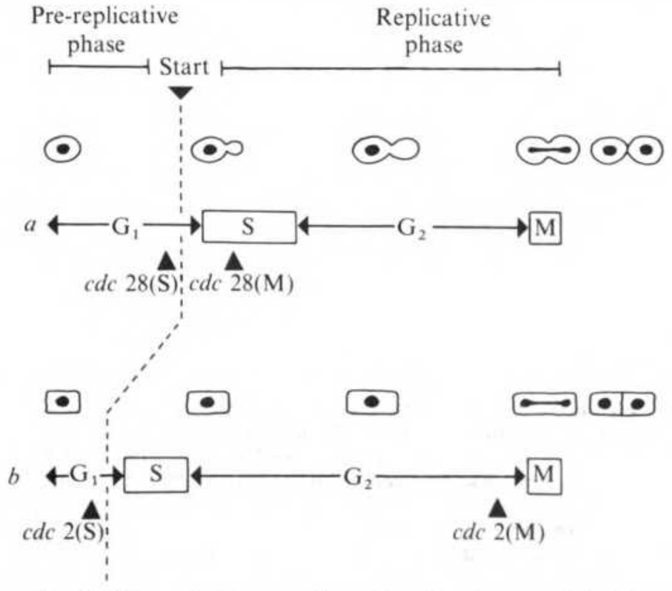

Fig. 1 Schematic representation of cell cycle control in *S. cerevisiae* (*a*) and *S. pombe* (*b*). Start divides the two cycles operationally into an uncommitted pre-replicative phase and a committed replicative phase. The pre-replicative phase occupies most of G$_1$. It is the major expandable part of the cycle, becoming much longer at slow growth rates. The figure represents rapidly growing cells in which the pre-replicative phase is longer in *S. cerevisiae* than in *S. pombe*. The transition or execution points of *cdc* 28 and *cdc* 2 are shown as filled triangles, the ones appropriate for start are labelled *cdc* 28(S) and *cdc* 2(S) and those appropriate for mitosis are *cdc* 28(M) and *cdc* 2(M).

there are any sequences in *S. cerevisiae* which have the same function as the *cdc* 2 gene. This can be done by introducing a *S. cerevisiae* gene bank into *S. pombe* and testing for complementation of the *cdc* 2.33 mutation. Previously, such complementation has only been observed for genes involved in intermediary metabolism such as *leu* 2 (refs 9, 10). A *S. cerevisiae* gene bank has been constructed in YEp13 (provided by K. Nasmyth), a vector which contains the *leu* 2 gene and can autonomously replicate in *S. pombe*. This gene bank was used to transform the *S. pombe* strain *cdc* 2.33 *leu* 1.32 in a manner identical to that described above for the isolation of pcdc2.3(Sp). A plasmid, pcdc2(Sc), was isolated which complemented the *cdc* 2.33 and *cdc* 2.M26 mutations. This plasmid contained *S. cerevisiae* sequences as its insert (data not given) and generated *cdc* 2$^+$ transformants having the same elongated appearance at the restrictive temperature as the *S. pombe* pcdc2.3(Sp) (Fig. 2*c*). Thus, *S. cerevisiae* contains DNA sequences which can functionally complement mutations in the *cdc* 2 gene.

S. cerevisiae cdc 28 can complement *cdc* 2

As *cdc* 2 is a start gene in *S. pombe*, pcdc2(Sc) might contain one of the four known *S. cerevisiae* start genes[5,6]. All of these have been isolated in the plasmids pcdc28, 36, 37 and 39 (ref. 8 and S. Reed, unpublished results) using vector YRp7 or its derivative YRp7′. The four plasmids were digested with *Hin*dIII and after Southern transfer were probed with ^{32}P-pcdc2(Sc). The hybridization observed in this experiment indicated that the inserts of pcdc2(Sc) and pcdc28 (containing the *cdc* 28 gene) contained common sequences. In particular, both plasmids had a 2.3-kb *Hin*dIII fragment in common. To test this was the same sequence, the 2.3-kb *Hin*dIII fragment was recovered from a digest of pcdc28, then nick-translated and hybridized to the similarly sized fragment from pcdc2(Sc) (Fig. 4). As the pcdc28 sequences are unique in the *S. cerevisiae* genome (S. Reed, unpublished results) this hybridization establishes that pcdc2(Sc) contains *cdc* 28 sequences. To confirm that pcdc2(Sc) contains a functional *cdc* 28 gene, the plasmid was transformed into a *cdc* 28.4 *leu* 2.3 *S. cerevisiae* strain (provided by I. Johnson). The resultant Leu$^+$ prototrophs grew at 36 °C, the restrictive temperature of *cdc* 28.4, demonstrating that pcdc.2(Sc) can complement a *cdc* 28 mutation and thus contains a functional *cdc* 28 gene. These experiments show that the *cdc* 28 gene contained within pcdc2(Sc) can complement mutations of *cdc* 2. To test whether the *cdc* 28 gene contained within pcdc28 will also complement mutations of *cdc* 2, the pcdc28 sequences first had to be transferred to a different vector because YRp7 cannot be selected for in *S. pombe*; pcdc28 was partially digested with *Sau*3A and ligated with *Bam*HI-digested pDB248. The crude ligation mix was used to transform the *cdc* 2.33 *leu* 1.32 *S. pombe* strain to Leu$^+$ prototrophy. About 30% of the transformants were able to form colonies at the restrictive temperature of 35 °C. The cells of these transformants were smaller (Fig. 2*c*) than wild-type cells (Fig. 2*a*) and were very similar to certain *wee* mutant alleles of *cdc* 2 (Fig. 2*d*). These *wee* mutant alleles have been interpreted as having an abnormally high *cdc* 2 gene product activity. Note that the behaviour of pcdc28 in *S. pombe cdc* 2.33 strains differs from that of pcdc2(Sc), which resulted in weaker complementation and the formation of elongated

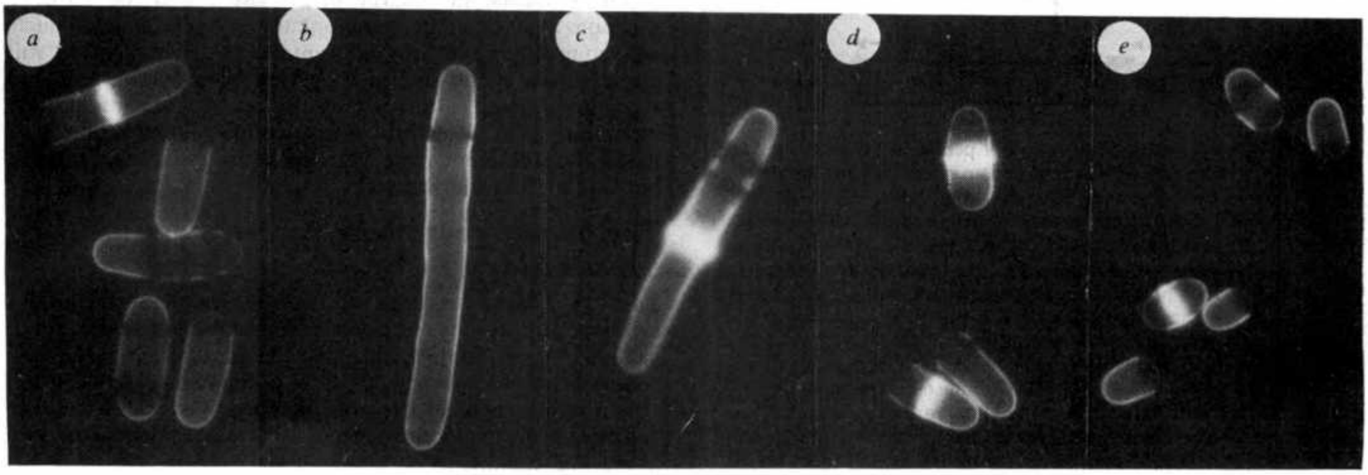

Fig. 2 Cells of *S. pombe* strains stained with Calcofluor and photographed by fluorescence microscopy. In these conditions the septa of dividing cells fluoresce intensely. *a*, Wild-type 972; *b*, *cdc* 2.33 *leu* 1.32; *c*, *cdc* 2.33 *leu* 1.32 containing pcdc2.3(Sp); *d*, *cdc* 2.1w (previously called *wee* 2.1); *e*, *cdc* 2.33 *leu* 1.32 containing pcdc28 in pDB248. Cells were grown in minimal medium at 25 °C overnight and were transferred to 35 °C in yeast extract medium for 7 h before staining as described in ref. 11. The cells in *e* include some dividing at a small size, similar to *cdc* 2.1w, and others which are highly elongated such as *cdc* 2.33 which have lost the plasmid and are unable to divide. pcdc2.3(Sp) is based on vector pDB262 which contains part of the yeast 2 μm circle, *leu* 2 and the bacterial plasmid pTR262. pDB248 is similar but with pTR262 replaced by pBR322[9,10].

cells (Fig. 2*c*). It is unknown why these two plasmids differ in their behaviour but as they were located in different vectors and were isolated from different gene banks the plasmid copy number and the flanking chromosomal and vector sequences could be different. Either of these two factors could influence the final activity of the *cdc* 28 gene product in *S. pombe*.

S. pombe cdc 2 cannot complement *cdc* 28

As *cdc* 28 can complement *cdc* 2 mutations of *S. pombe*, it was of interest to determine whether *cdc* 2 could complement *cdc* 28 mutations of *S. cerevisiae*. This was tested by transforming the *S. cerevisiae* strain *cdc* 28.4 *leu* 2.3 to Leu$^+$ prototrophy using pcdc2.3(Sp). The Leu$^+$ transformants did not grow at 36 °C, forming enlarged cells that were both budded and unbudded. This failure to complement indicates that the *S. pombe cdc* 2 gene cannot substitute for a defective *cdc* 28 gene in *S. cerevisiae*, which could be due to inadequate *cdc* 2 expression or inability of the *cdc* 2 gene product to provide the entire function of *cdc* 28. It has been shown that the 5′ regulatory sequences of the cytochrome *c* and alcohol dehydrogenase genes differ in *S. pombe* and *S. cerevisiae* (ref. 13 and P. Russell, personal communication). Thus the 5′ sequences of *cdc* 2 may be unable to initiate transcription at a sufficient level in *S. cerevisiae* to complement mutations of *cdc* 28.

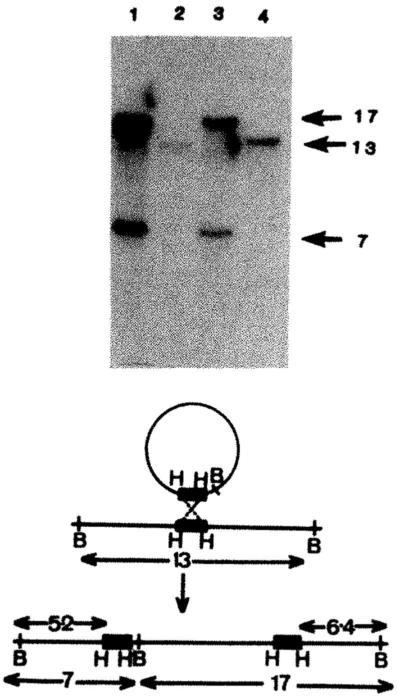

Fig. 3 A model of the integration of pcdc2.32(Sp) into the *cdc* 2 site on chromosome II (bottom) and an insert showing Southern blot transfers of *S. pombe* chromosomal DNA digested with chromosomal DNA (top) prepared from: tracks (1) and (3), pcdc2.32(Sp) integrants; tracks (2) and (4), the *leu* 1.32 strain before integration. B, *Bam*HI sites; H, *Hin*dIII sites. All procedures for DNA preparation, nick-translation with ^{32}P-CTP and Southern blot transfers are described in refs 9, 10. The fragments produced by integration can be explained as follows. The 1.4-kb *Hin*dIII fragment (shown as a thick line) derived from pcdc2.3(Sp) is contained within a 13-kb *Bam*HI chromosomal fragment. When pcdc2.32(Sp) of total length 11 kb integrates via homologous recombination at the *cdc* 2 site, a tandem duplication of the 1.4-kb *Hin*dIII fragment is formed which flanks the vector sequences of pDAM6. As pcdc2.32(Sp) contains only one *Bam*HI site situated in the vector next to the chromosomal insert, two new *Bam*HI fragments are generated with a combined length of 24 kb made up of the original *Bam*HI chromosomal fragment of 13 kb and pcdc2.32(Sp) (11 kb). The precise sizes of the two *Bam*HI fragments generated can be explained if it is assumed that the 1.4-kb *Hin*dIII fragment is located 5.2 and 6.4 kb from the chromosomal *Bam*HI sites.

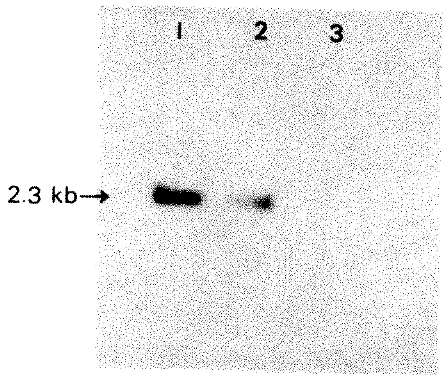

Fig. 4 Southern blot transfers of DNAs digested with *Hin*dIII and probed with the 2.3-kb *Hin*dIII fragment derived from pcdc28 (see text). Track (1), pcdc28; (2), pcdc2(Sc); (3), YEp 13. Note that a single 2.3-kb fragment hybridizes in pcdc28 and pcdc2(Sc) but there is no hybridization with YEp 13. All procedures for DNA preparation, nick-translation with ^{32}P-CTP and Southern blot transfers have been described elsewhere[9,10].

cdc 2 and *cdc* 28 genes perform similar functions in both G_1 and G_2

The requirement for the *S. pombe cdc* 2 gene in G_1 at start has already been described; *cdc* 2 is also required in G_2 before mitosis (Fig. 1). Whether cells become blocked in G_1 or G_2 depends on their position in the cell cycle at the time of temperature shift[7]. It has recently been shown that certain *cdc* 28 mutants of *S. cerevisiae* also arrest in G_2 just before mitosis as well as in G_1 at start[14]. Thus *cdc* 28 also has a dual role in the cell cycle at start and at mitosis, and is presumably providing both these functions when complementing *cdc* 2 mutations of *S. pombe*. This strongly suggests that the molecular function of the *cdc* 2 and *cdc* 28 genes is the same or very similar. To determine whether the *cdc* 2 and *cdc* 28 sequences are also closely related, pcdc2.3(Sp) was digested with *Hin*dIII and after Southern transfer was hybridized with ^{32}P-pcdc2(Sc). No hybridization of the inserts was detected in normal stringency conditions (0.75 M NaCl, 65 °C). This lack of sequence homology is not surprising as the two yeasts are not closely related and no hybridization was observed between *S. pombe leu* 1 and *S. cerevisiae leu* 2 genes, both of which encode the same enzyme, β-isopropylmalate dehydrogenase[9,10]. DNA sequencing will be required to establish the precise relationship between *cdc* 2 and *cdc* 28.

The molecular mechanism of the *cdc* 2 and *cdc* 28 gene functions at start and mitosis is unknown. As the gene products are required for two very different cell cycle events, they will possibly have some sort of triggering coordinating role. We envisage a molecular function such as that of protein modifications in the control of many other cellular processes[15], modulating different molecular activities at start and mitosis, but via the same mechanism.

The mitotic controls in *S. pombe* and *S. cerevisiae*

The *cdc* 2 gene function has been shown to be the major rate-limiting step in *S. pombe*, determining the timing of mitosis[16,17]. *wee* mutant alleles at the *cdc* 2 locus result in a cell cycle having a shorter G_2 than normal and a reduced cell size at mitosis and cell division. Before mitosis can occur, the cell must grow to a critical size and this requirement is reduced in the *wee* mutants[25,26].

In *S. cerevisiae* there is no mitotic control analogous to that found in *S. pombe*. Mitosis is thought to occur when a certain time has elapsed after 'start'[18,19]. The difference in control between the two yeasts may be related to the fact that mitosis is apparently initiated very early in the cell cycle in *S. cerevisiae*. A short intranuclear spindle forms by the end of G_1 (ref. 20). This structure elongates later in the cycle to form the full mitotic spindle during mitosis. The requirement of *cdc* 28 for mitosis is also completed early, about one-tenth of a cell cycle after start (Fig. 1; ref. 14). These observations suggest that the initiation of mitosis occurs early in the cell cycle in *S. cerevisiae*, a situation which is different from most eukaryotic cells such as *S. pombe*. When *cdc* 28 is introduced into *S. pombe* as pcdc28, mitosis is initiated prematurely so that cell division occurs at a small size (Fig. 2*e*). One explanation for this could be that the *cdc* 28 gene lacks some of the regulatory functions of *cdc* 2 which ensure that mitosis is delayed until the *S. pombe* cell has grown to normal size. *cdc* 28 may not have these functions because this control is not normally operative in *S. cerevisiae*.

Cell cycle control in other organisms

The *cdc* 2 and *cdc* 28 genes have major roles in the cell cycle control of *S. pombe* and *S. cerevisiae* and must perform identical or similar molecular functions. But the two organisms are not closely related as judged by both taxonomic criteria[21] and the comparison of 5S RNA[22] and cytochrome *c*[23] sequences, which show <70% homology. Despite this considerable evolutionary divergence, the molecular mechanisms of start and of the control initiating mitosis appear to have been highly conserved, thus we believe that these control mechanisms may also be applicable to other eukaryotes. In mammalian cells, G_1 restriction or transition points analogous to start in the yeasts have been proposed as the major point of cell cycle control[24]. Thus it is possible that the control in mammalian cells may also involve a functional equivalent of the *cdc* 2 and *cdc* 28 gene products.

We thank Melanie Piper and Rachel McIntosh for technical assistance, and Steve Reed, Kim Nasmyth and Irving Johnson for generously providing genes, banks and strains. Financial support was provided by the SERC, MRC and CRC.

Arrangement of human immunoglobulin heavy chain constant region genes implies evolutionary duplication of a segment containing γ, ε and α genes

J. G. Flanagan & T. H. Rabbitts

Laboratory of Molecular Biology, The MRC Centre, Hills Road, Cambridge CB2 2QH, UK

Cosmid clones containing the human γ, ε *and* α *heavy chain constant region genes and an* ε *pseudogene have been isolated. All these genes have a switch sequence detectable by hybridization. We have studied overlapping cosmids covering two separate regions of the genome, and the gene order in each of these regions was found to be* γ–γ–ε–α. *This implies an evolutionary duplication in this multigene family involving* γ, ε *and* α *genes.*

MOST known mammalian genes are organized in multigene families whose members share sequence homology. Such families include the globin genes[1,2], interferon genes[3], growth hormone genes[4], genes of the major histocompatibility complex[5] and immunoglobulin genes. The immunoglobulin heavy (H) chain genes consist of four linked families of gene segments: the variable (V_H), diversity (D), joining (J_H) and constant (C_H) gene segments. The C_H gene segments determine the class of the H-chain polypeptide. Both man and mouse have five classes of H chain, known as μ, δ, γ, ε and α, which differ in their biological activities. In both species the γ chains are further divided into four subclasses, and in man there are two subclasses of α chain. When the active H-chain gene is formed by $V_H/D/J_H$ integration[6–8] the C_H gene closest to the J_H locus, the μ gene, is the first to be expressed while the other C_H genes can subsequently be expressed by H-chain switching mechanisms. One of these mechanisms, which operates for each C_H gene except δ, involves deletion of all C_H genes between the V gene and the newly expressed C_H gene[9–12]. This switch deletion has been proposed to involve recombination, perhaps by unequal sister chromatid exchange[13–15], between homologous, internally repetitive sequences (called switch or S regions) which were found upstream of each mouse C_H gene except δ[14,16–18]. It was similarly found in man that the μ gene S region has a repetitive sequence and is homologous with a region upstream of $\gamma2$ but not δ[19]. Comparison of S regions of mouse μ, γ and α genes with their human counterparts has shown strong evolutionary conservation [19–22].

The order of the C_H genes in the mouse has been determined as $5'$-μ-δ-$\gamma3$-$\gamma1$-$\gamma2b$-$\gamma2a$-ε-α-$3'$, and no pseudogenes have been reported[18]. The existence of two α-chain subclasses in man and the finding that human DNA contains a pseudo γ gene ($\psi\gamma$)[22,23] and three ε-like genes[24–26] implied that the arrangement of human C_H genes was different from that in the mouse. Some aspects of the arrangement of human C_H genes have already been published. The J_H–μ–δ region was mapped and found to be organized similarly to the mouse[19,27], the $\gamma2$ and $\gamma4$ genes were shown to be about 19 kilobases (kb)

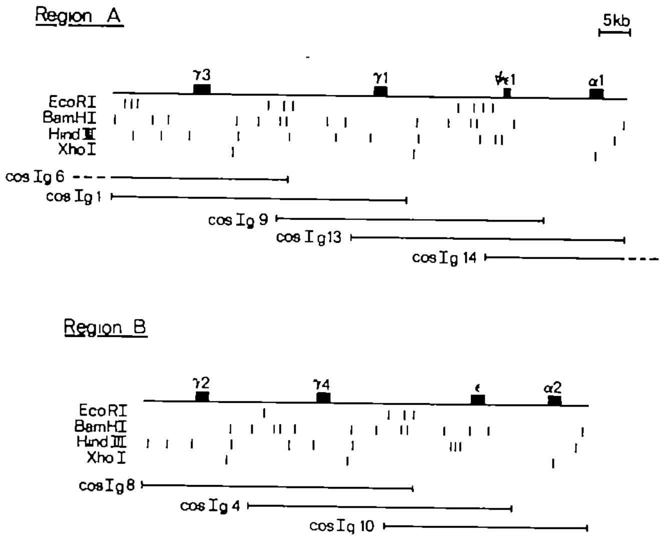

Fig. 1 Restriction maps of two regions of human DNA covered by overlapping cosmid clones. The cosmids were digested with the four enzymes shown, singly and in all pairwise combinations. Restriction fragments were separated on 0.8% agarose gels, and after reducing the fragment sizes by treatment with acid and then base[37], the DNA was blotted on up to four filters sequentially[38]. Each filter was hybridized to one of four probes: γ, ε or α gene probes as described in the text or the cosmid vector pOPF1 (F. Grosveld, personal communication). Overlaps between cosmids were confirmed by running all corresponding digests of overlapping clones in adjacent slots of agarose gels. The ends of cosIg6 and cosIg14 which extend beyond region A are shown as dotted lines because the restriction map in these regions has not been confirmed by comparison with other cosmid or phage λ clones.

apart[22,23,28], and it was reported that the ε and ψε1 genes are each linked to an α gene[24]. The ψε2 gene is apparently a processed pseudogene which has lost its intervening sequences, has a poly(A)-rich tail and has been conveyed to a new chromosomal location[24]. We wanted to study the organization of the human C_H genes further both to allow an evolutionary comparison with the mouse and also to allow a comparison of the H-chain genes of normal humans with those of individuals with immune deficiencies or leukaemias such as Burkitt's lymphoma. We present here a partial characterization of the C_H gene locus in man. Cosmid clones were isolated which apparently contained all the expressed γ, ε and α genes and ψε1. All of these genes have switch sequences which hybridize to S_μ. By mapping overlapping cosmid clones we identified two separate blocks of C_H genes, each with the order γ–γ–ε–α, implying an evolutionary duplication involving γ, ε and α genes. We propose an order of these two blocks of genes relative to each other and relative to the $J_H/\mu/\delta$ region.

Isolation and restriction mapping of cosmids containing γ, ε and α genes

Approximately 5×10^5 colonies of a human genomic cosmid library (F. Grosveld, personal communication) were screened with human γ and ε C_H gene probes. The γ probe was the 3.6-kb *Eco*RI–*Hin*dIII insert of p3.6RH4.2 (ref. 23) which contains the whole γ3 gene, while the ε probe was the 2.0-kb *Bam*HI–*Pst*I insert of ε1.2BP25 (ref. 25) which contains an entire ε gene. Several cosmid clones were isolated with these probes. Restriction mapping showed that the cosmids fall into two separate groups of overlapping clones, each group representing an unbroken region of chromosomal DNA, termed here region A and region B (Fig. 1). γ, ε and α genes were found in each region and located within the regions by hybridization to the γ or ε probes described above or to a mouse α cDNA probe consisting of the 0.6-kb *Eco*RI fragment from the 3′ end of the insert of p107αR5 (ref. 29). Both regions A and B were found to have a gene order γ–γ–ε–α. The total sizes of regions A and B are approximately 83 and 72 kb, respectively, and the distance between genes within each region ranges from 10 to 26 kb, which is similar to the spacing found between mouse γ, ε and α genes[18]. It is unlikely that the cosmids have undergone deletions because all parts of region A are covered by at least two cosmids, and although the terminal areas of region B are covered by only one cosmid, our map in those areas is corroborated by published maps of phage λ clones[22–26,28].

Characterization of genes present in cosmid clones

We obtained evidence by restriction mapping and hybridization as described above for four γ, two ε and two α class genes in the cosmids which we isolated. These genes were assigned to subclasses by sequencing or, in the case of some of the genes for which sequences were already available, by restriction mapping. However, we have not yet fully sequenced any of the genes present in these cosmids, so the subclass assignments remain provisional.

Restriction maps and partial sequences were known which distinguished the four γ subclass genes and the ψγ gene (U. Krawinkel and T.H.R., unpublished results and refs 22, 23, 28), so we could identify the γ genes in the cosmids on the basis of the restriction maps shown in Fig. 1. Apparently, the cosmids contain the γ1, γ2, γ3 and γ4 genes, but not ψγ. In the case of the γ1 and γ3 genes, this identification was confirmed by sequencing their distinctive hinge regions. Each hinge coding segment begins with a *Pst*I site[23], so *Pst*I fragments of cosIg1 and cosIg13 were subcloned into M13mp9 (ref. 30) and subclones containing hinge region fragments were selected by hybridization with the 1.8-kb *Pst*I fragment of p3.6RH4.2, which contains the fourth hinge of γ3. These clones were sequenced by the chain terminator method[31], giving sequences which agree with those previously published for the γ1 hinge coding segment and the four hinge coding segments of γ3 (data not shown). Identical γ1 hinge region sequences were obtained from cosIg1 and cosIg13, confirming the overlap between these two clones.

The ε gene in region B (Fig. 1) was identified as the active gene by restriction site comparison with the expressed ε gene of an IgE-producing myeloma, which is contained in the λ clone λε1.2 (ref. 25). Southern blot hybridization using the ε probe ε1.2BP25 showed that cosIg4, cosIg10 and λε1.2 have identical

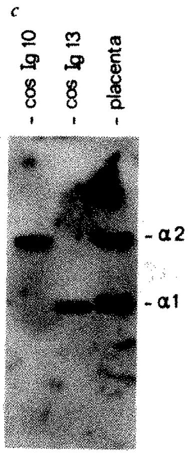

Fig. 3 Partial sequences of the putative $\alpha 1$ (*a*) and $\alpha 2$ (*b*) genes. *c*, Southern blot comparing α genes in cosIg10, cosIg13 and placental DNA. **Methods:** The 3.2-kb *Xho*I–*Hin*dIII fragments of cosIg10 and cosIg13 were subcloned in M13mp9[30] and sequenced from the *Xho*I site by the chain terminator method[31]. The deduced amino acid sequence is shown in the single letter code above the nucleotide sequence, and an arrow marks the splice site at the end of the C_H2 domain. Residues known to differ between the α_1 and α_2 proteins are boxed[32]. In *c*, all the DNAs were digested with *Pst*I, fractionated on a 1.4% agarose gel and blotted onto a nitrocellulose filter[39]. The DNA was then hybridized with 2×10^6 c.p.m. per ml of nick-translated α2XP8 at 65 °C with a salt concentration of $1\times$SSC and washed at 65 °C with $0.1\times$SSC[40]. The filter was then exposed to preflashed film at −70 °C with an intensifying screen[41].

sites for *Bam*HI, *Pst*I, *Sal*I, *Bgl*II, *Sma*I, *Pvu*II and *Hinc*II, at a total of nine sites distributed in and to either side of the ε gene. This result confirms the overlap between cosIg4 and cosIg10 and indicates that these cosmids contain the active ε gene which has been sequenced previously[24,25].

The ε gene detected by hybridization in region A (Fig. 1) was found by nucleotide sequencing to be an unusual type of pseudogene. Hybridization of the insert of ε1.2BP25, which contains all four coding segments of the active ε gene, was confined to a 2.0-kb *Hin*dIII–*Bam*HI fragment of cosIg13. This fragment was subcloned in M13mp8 (ref. 30) and sequenced, by the chain terminator method, 374 bases from the *Hin*dIII site (Fig. 2). For the first 313 bases this sequence shows homology to the S_μ region repeats but thereafter it is identical with the sequence of the active ε gene, except that it starts four bases into the $C_\varepsilon3$ coding segment. The $C_\varepsilon3$ segment therefore lacks an acceptor RNA splice site. We obtained other sequences homologous to $C_\varepsilon3$ and $C_\varepsilon4$ of the active ε gene by sequencing *Hpa*II fragments of cosIg13 (data not shown). Although the ε gene in cosIg13 contains $C_\varepsilon3$ and $C_\varepsilon4$ sequences, we found no evidence of $C_\varepsilon1$ or $C_\varepsilon2$ sequences by hybridization to the ε1.2BP25 probe. This gene thus seems to be a pseudogene which has lost the first two coding segments of an active ε gene by a deletion which fused an S-like sequence to a site just inside the $C_\varepsilon3$ coding segment. This deletion is apparently not a cloning artefact because the ε1.2BP25 probe hybridizes to a *Hin*dIII–*Bam*HI fragment of the same size in human genomic DNA and in cosIg13 (data not shown). Similar information was recently reported from studies on a phage λ clone, apparently describing the same ε pseudogene, which was called $\psi\varepsilon1$ (ref. 24). The structure of the $\psi\varepsilon1$ gene is strikingly analogous to the mouse myeloma IF2 mutant gene in which the internally repetitive switch sequences were first noted[14]. In both the $\psi\varepsilon1$ gene (which is a germ-line mutation) and the IF2 mutant (which is an *in vitro* mutant of a γ1-secreting myeloma cell line), sequences which are homologous to the S region have been joined to a site within a gene. In the former case this site is just within a coding region while in the latter it is within an intervening sequence, just before a coding region. Evidently, aberrant rearrangements involving S sequences are important in the formation of these mutations.

Preliminary identification of the α genes present in cosmid groups A and B was achieved by partial nucleotide sequencing and comparison of the derived amino acid sequences with the known $\alpha1$ and $\alpha2$ protein sequences. The mouse α probe described earlier (which contains only $C_\alpha2$ and $C_\alpha3$ sequences) hybridizes to a 3.2-kb *Xho*I–*Hin*dIII fragment of both cosIg13 (region A) and cosIg10 (region B). This fragment of each cosmid was subcloned in M13mp9 and more detailed restriction mapping of the subclones showed that in each case the *Xho*I site is within the α gene. The M13 subclones were therefore sequenced from the *Xho*I site towards the *Hin*dIII site, yielding the sequences shown in Fig. 3*a* and *b*. These sequences cover almost all of the $C_\alpha2$ domain, over a region where the $\alpha1$ and $\alpha2$ protein sequences are known to differ at seven characteristic amino acid residues[32]. Our deduced amino acid sequences for the genes in cosIg13 and cosIg10 correspond exactly to published protein sequences for $\alpha1$ and $\alpha2$, respectively[32], except for differences or ambiguities of amide assignment which are probably due to technical problems of protein sequencing. It therefore seems likely that the α gene in cosIg13 is $\alpha1$ and that in cosIg10 is $\alpha2$.

To confirm the hypothesis that cosIg13 and cosIg10 contain the active $\alpha1$ and $\alpha2$ genes we examined the number of α genes in human genomic DNA by Southern filter hybridization. Figure 3*c* shows a Southern blot comparing placental genomic DNA, cosIg13 and cosIg10, all digested with *Pst*I. The blot was hybridized to subclone α2XP8, which contains a 0.6-kb fragment of cosIg10 extending from the *Xho*I site near the start of $C_\alpha2$ to a *Pst*I site in $C_\alpha3$. The genomic DNA shows only two bands: a 2.0-kb band co-migrating with the band from cosIg10 and a 1.2-kb band co-migrating with the band from cosIg13. As no other hybridizing bands were detected, it seems likely that only two α genes exist in the genome and that the genes which we have cloned and partially sequenced are the active $\alpha1$ and $\alpha2$ genes. However, we cannot rule out the possibility that each band detected by Southern blotting in genomic DNA represents more than one gene. This caveat also applies to the γ and ε genes.

All the γ, ε and α genes have S regions homologous to S_μ

The H-chain class switch in antibody secreting cells is believed to be mediated by recombination between homologous S sequences near each C_H gene except δ. If this is correct we would expect to find that the human μ, γ, ε and α genes have homologous S sequences. We have studied this possibility by hybridization of an S probe, derived from the human μ gene, with human γ, ε and α genes. Figure 4 shows a Southern blot hybridization in which a restriction fragment containing S_μ was used to probe cosmids containing all the γ, ε and α genes described here and $\psi\varepsilon1$. As expected, all these genes, including

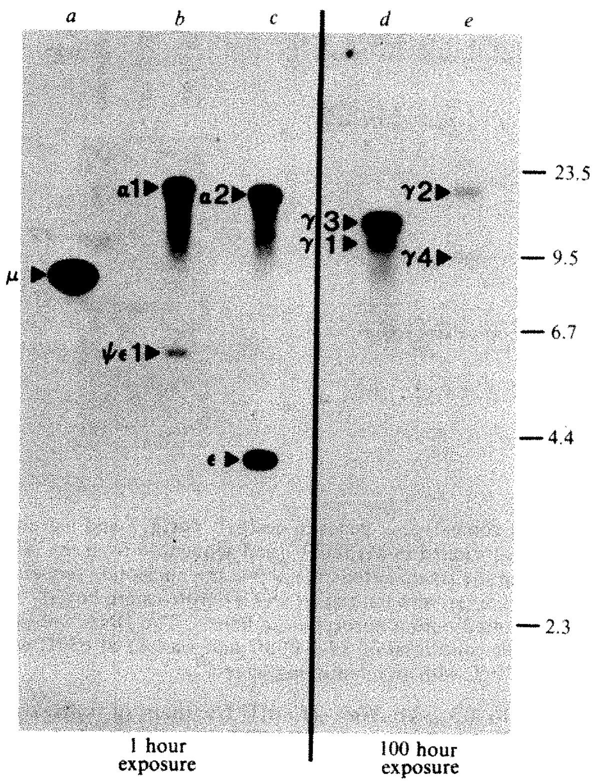

Fig. 4 Southern filter hybridization between an S_μ probe and S regions of other C_H genes. The probe was a 5.0-kb fragment of C76R51 (a subclone which contains the 8-kb *Eco*RI fragment from the 5′ end of λC76[19]) extending from an *Eco*RI site 45 base pairs inside the μ gene to a *Hin*dIII site in the 5′-flanking region of the μ gene. The restriction digests were as follows: *a*, cosIg1 × *Bam*HI; *b*, cosIg8 × *Bam*HI and *Eco*RI; *c*, cosIg10 × *Bam*HI; *d*, cosIg13 × *Bam*HI; *e*, C76R51 × *Eco*RI. Restriction fragments were separated on a 0.8% agarose gel and blotted onto a nitrocellulose filter[39]. The filter was then hybridized with 2×10^6 c.p.m. per ml of nick-translated probe in low stringency conditions: the hybridization and all washes were at 65 °C at a salt concentration of 6 × SSC[40]. The filter was then autoradiographed at −70 °C with an intensifying screen[41] for the times indicated.

$\psi\varepsilon_1$, have an S sequence which hybridizes to S_μ. This observation is consistent with a role for the S sequences in H-chain switching. However, even in the conditions of low hybridization stringency used here, S_μ hybridizes to S_γ very weakly—about two to four orders of magnitude more weakly than to S_ε or S_α. Among the γ genes, $S_\gamma 3$ hybridizes about 20–50 times more strongly with S_μ than do the other S_γ regions. Similar observations were made on mouse C_H genes[18], and the relative sequence divergence of S_γ raises questions about the H-chain switch mechanism. It has been suggested that sequences other than the S region repeats may be involved in switching[33], and it has also been proposed, on the basis of S-region homologies in the mouse, that γ genes are expressed initially by a switch from μ to the γ gene closest to μ, which can be followed by a switch from this γ gene to the other γ genes[34]. In support of this latter proposal, we find that in humans, as in mice, the γ gene which seems to be closest to μ (that is, the γ3 gene, see below) has the S_γ region which hybridizes most strongly to S_μ.

Order of the cosmid groups within the C_H locus

The cosmid clones described here fall into two groups which do not appear by their restriction maps to overlap either with each other or with the region around the μ and δ genes cloned in phage λ (refs 19, 27). However, we can predict the order of the two groups relative to each other and relative to the $J_H/\mu/\delta$ region by considering known deletions in an IgE-producing myeloma and two individuals with antibody deficiencies which are described in an accompanying paper[35]. It has previously been shown by Southern blotting that the IgE-producing myeloma 266B1 has undergone a deletion of ψε1 (refs 25, 26). During the H-chain class switch all C_H genes between J_H and the newly expressed C_H gene are deleted, so assuming that the deletion in myeloma 266B1 results from H-chain switching, ψε1 must lie between the J_H region and the active ε gene. Therefore, region A (containing ψε1) apparently lies between the $J_H/\mu/\delta$ region and region B (containing ε). Further support for this gene order comes from our accompanying paper, where we show that individuals lacking α1 antibodies and certain γ subclasses have a DNA deletion involving ψε1, the presumptive α1 gene and three γ genes (apparently γ1, γ2 and γ4)[35]. These data can be explained by a large inherited deletion which suggests the same order of the C_H genes as the deletion in the IgE-producing myeloma does. The overall gene order would therefore seem to be 5′–J_H–8 kb–μ–5 kb–δ– – – – γ_3–26 kb–γ1–19 kb–ψε1–13 kb–α1– – – – γ2–18 kb–γ4–23 kb–ε–10 kb–α2–3′. With the blocks of genes arranged in this way, all the genes have the same transcription orientation. The cosmid clones described here did not contain the two other known human C_H pseudogenes, ψε2 and ψγ, so we cannot comment on the location of those genes.

Evolution of the C_H gene locus

We have shown here that the C_H gene organization of man is strikingly different from that of the mouse in that human γ, ε and α genes are interspersed with each other, whereas in the mouse the four γ genes are clustered upstream of the single ε and α genes. This arrangement in man probably results from duplication of a large chromosomal region containing γ, ε and α genes. Two models for the evolution of the human C_H locus

γ2 γ4 ε α2

Fig. 5 Two models for the evolution of the human immunoglobulin C_H gene locus. The position of the ψγ gene is not known. ψε2 is apparently on a separate chromosome[24].

are illustrated in Fig. 5. The large ancestral segment which was duplicated may have had a gene order of either γ-γ-ε-α or γ-ε-α. In either case it is significant that when the protein sequences[36], gene sequences[22] and flanking restriction site patterns (Fig. 1) of the four human γ genes are compared, it is clear that $\gamma 3$ and $\gamma 1$ are particularly closely related to each other, as are $\gamma 2$ and $\gamma 4$. If a segment with the gene order γ-γ-ε-α duplicated (Fig. 5*B*), then the γ gene homologies suggest the operation of gene correction mechanisms such as gene conversion which have kept adjacent γ genes similar. Alternatively, the homologies can be explained by initial duplication of a segment with the gene order γ-ε-α, (Fig. 5*A*), followed by further duplications of the γ genes. γ_2 and γ_4 could have arisen by a simple gene duplication. The production of γ_3, γ_1 and $\psi\gamma$ is evidently more complex, because γ_3, unlike the other γ genes, has four hinge exons, the most 5′ of which is closely related to the single $\psi\gamma$ hinge exon while the other three are closely related to the single γ_1 hinge exon[22,23]. It has been proposed that $\gamma 3$ was created by an unequal cross-over between $\gamma 1$ and $\psi\gamma$ ancestors, thus implying a gene order $5'$-$\gamma 1$-$\gamma 3$-$\psi\gamma$-$3'$ (ref. 22). Our results do not seem compatible with this idea but suggest that exon duplication led to four γ_3 hinges originally all of the $\gamma 1$ type, followed by a gene conversion between the $\psi\gamma$ hinge and the first hinge of $\gamma 3$.

Several mechanisms have evidently contributed to the evolutionary diversification of the human immunoglobulin C_H gene cluster, including exon deletion in $\psi\varepsilon 1$, exon duplication in $\gamma 3$, possibly gene conversion between γ genes, duplication of individual γ genes and duplication of a large chromosomal segment containing three different types of gene—the γ, ε and α genes. An interesting possibility is the involvement of S segments or their precursors in certain evolutionary changes in this region such as the duplication of C_H genes. It may be possible to derive a more precise description of the events in the evolution of the C_H gene locus from a study of the DNA of other primates. In any case, the structure of the human C_H gene locus, which has emerged to be substantially different from that of the mouse, clearly reveals a high degree of evolutionary flexibility in the development of this multigene family.

We thank F. Grosveld for providing the cosmid library and the cosmid vector pOPF1, F. Groveld and D. Kioussis for helping us to screen the library, M.-P. Lefranc for help in subcloning the α genes, L. Hood for the mouse α cDNA clone p107αR5 and A. Forster for technical assistance.

The expression in normal rat cells of modified polyoma virus genomes, separately encoding large T, middle T or small T antigens, has allowed the investigation of the roles of these proteins in oncogenic transformation. Middle T is sufficient to transform cells of established lines but the transformants are serum dependent. Large T lacks intrinsic oncogenic potential but can relieve the serum dependence of normal and transformed cells. Middle T alone cannot transform primary rat embryo fibroblasts.

GENETIC analysis of the respective roles in oncogenic transformation of the three known polyoma virus early proteins, large T, middle T and small T[1–4], is complicated by the overlapping organization of the coding sequences in the viral DNA[5–7] (Fig. 1). The superimposed information content of the genomic DNA, contained in alternate translational reading frames, is resolved *in vivo* by differential processing of a common primary early region transcript: single introns of different lengths and positions are excised to produce three distinct mRNAs which individually encode the proteins. Application of the contemporary gene transfer techniques to study the biological functions of the viral early proteins would be facilitated by prior resolution of the coding information at the DNA level. This was achieved initially for the middle T protein[8] and more recently for the large T and small T proteins[9,10] by precise deletion of intron sequences from otherwise full-length viral DNA cloned in a plasmid vector. Introns were removed by replacing genomic restriction fragments spanning them with the corresponding shorter fragments derived from cDNA clones[11]. The three

§ The common N-terminal polypeptide expected from translation in the middle T/small T frame up to the out-of-phase deletion (~10,000 daltons) has not been unambiguously identified in cells infected with the NG18 mutant, although mRNAs with the appropriate splices are synthesized (our unpublished results and G. Carmichael and T. Benjamin, personal communication).

recombinants generated (Fig. 1, Table 1) were designated pPyLT1, pPyMT1 and pPyST1 to indicate the intron deleted. Separate transfer of the modified genomes into cultured cells results in the production of the expected single early protein (refs 8, 9 and Z. Zhu, G. M. Veldman, A. C., A. C. and R. K., manuscript in preparation) through the efficient expression of unspliced mRNAs.

Many studies on polyoma virus-induced transformation[12–20] have pointed to a critical role for the middle T protein, without excluding an involvement of all or parts of the other two early gene products. Experiments done with temperature-sensitive mutants of the large T protein have indeed suggested a role for the amino-terminal region of this protein in the maintenance of the transformed state in cell lines derived from FR3T3 rat cells[21]. The first set of results obtained with the modified viral genomes encoding only one of the early proteins showed that DNA of the middle T plasmid pPyMT1 transformed rat cells of the F2408 established line only slightly less efficiently than did cloned wild-type DNA. Transformed lines were obtained which synthesized the middle T, but neither the large T nor the small T protein. They grew in agar and to high density on plastic when tested in medium supplemented with 5% fetal calf serum. The 'middle-T-only' lines assayed for oncogenicity all induced tumours in young Fischer rats in a manner indistinguishable from that of control lines producing all three early proteins. Although it was therefore clear for the first time that middle T expression alone is sufficient to initiate and to maintain an oncogenic state, significant alterations in cell physiology caused by the expression of large T and/or small T were still not exlcuded. It was suggested[8] that if middle-T-only transformants could be shown to differ from other polyoma virus-transformed cells in some selectable property, it might be possible to assay for functions of the other viral proteins by transfer into the cells of appropriately modified genomes. We report here that such a property does exist. Cells transformed by plasmid pPyMT1 have a conditional defect in the expression of the tranformed state: they revert to an apparently normal phenotype when grown in low serum medium. We show that the ability to maintain transformation at low serum concentration, which is characteristic of cells transformed by wild-type viral DNA, is specifically complemented by modified viral genomes that encode either all of the large T protein or only its N-terminal 40%. The same DNAs, while lacking transformation potential, could be used to derive FR3T3 lines with substantially reduced serum dependence. These results motivated us to ask whether the requirements for transformation of primary embryo fibroblasts differ from those of established cells lines. Successful transformation of these cells was achieved with cloned wild-type DNA, but not with any of the modified genomes separately encoding the early proteins.

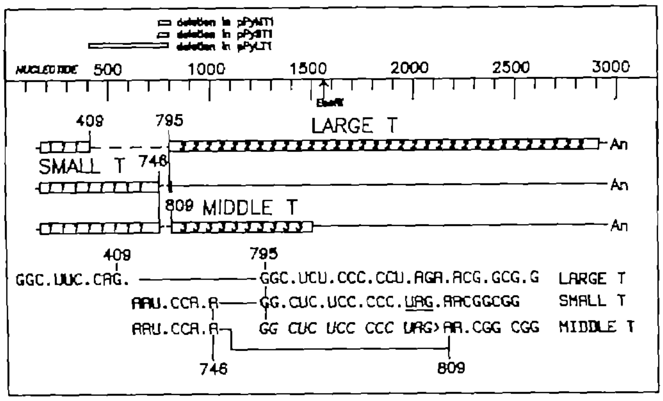

Fig. 1 Expression of the polyoma virus early region. A linearized map of the early region DNA is shown, marked with conventional nucleotide numbers[37] and the reference cutting site for endonuclease *Eco*RI. The three different spliced mRNAs are aligned with the map Coding regions are boxed, non-translated regions are represented by continuous lines and introns by dashed lines. Numbers within the coding regions indicate the translational reading frame used; note that the 3′ exon of the small T protein mRNA is translated in frame 1. RNA sequences across the splice junctions are shown in the lower part of the figure to illustrate how the joining of the two 5′-splice sites with two 3′-splice sites in three of the four possible combinations accomplishes the changes in codon reading frame required to use the two open frames available between nucleotides 809 and 1,497. The positions of the specific intron deletions in the viral genomes of plasmids pPyMT1, pPyLT1 and pPyST1 (see Table 1) are illustrated at the top of the figure.

Transformation of FR3T3 cells by DNA encoding only the middle T protein

The transforming activities of recombinant plasmids (Table 1) containing genes uniquely encoding large T (pPyLT1), middle T (pPyMT1) or small T (pPyST1) were tested with a Fischer rat cell line of the 3T3 type[22], FR3T3[23]. A recombinant containing unmodified viral DNA (pPY1) served as the control. DNA was transferred into cells by fusion with bacterial protoplasts[24]. Frequencies of transformation were measured by focus formation in medium containing 10% calf serum (Table 2). As expected from previous results with *hrt* mutants[25–27] (which express only the large T protein), plasmid pPyLT1 did not transform. Plasmid pPyMT1 transformed FR3T3 cells with a somewhat lower efficiency than the control plasmid pPY1, a result similar to that previously reported for F2408 cells[8]. Plasmid pPyST1, which encodes only the small T protein, did not transform. Additional plasmids were also negative: pNG1[21], including the entire genome of the partial large T intron deletion mutant NG18 that expresses only the large T protein[25–27]; pLT214, including a fragment of the viral DNA insert from pPyLT1 spanning the 5′ half of the early region and encoding an N-terminal truncated form of the large T protein (334 virus-coded amino-acid residues plus 16 C-terminal residues from vector sequences); pMC1[21], including the corresponding fragment from pNG1 and also encoding a truncated large T protein. Data shown in Table 2 for primary rat embryo fibroblast cultures will be discussed below.

Serum-dependent growth properties of transformants expressing only middle T protein

As illustrated in Fig. 2, FR3T3 cells grow to the monolayer stage in medium supplemented with 10% calf serum (*a*), but are unable to divide in only 0.5% serum (*b*) and die in growth medium without serum (*c*). Transformation with wild-type polyoma virus DNA, represented in Fig. 2 by the PYT21 line, derived by transfer of plasmid pPY1, enables the cells to grow past the monolayer stage to high density in either 10% (*a*) or 0.5% (*b*) serum, and also to grow relatively well without exogenous serum factors (*c*). By contrast, all lines derived from FR3T3 by transfer of pPyMT1 ('MTT' lines) grew to high density in 10% serum (*a*), but stopped at confluence in 0.5% serum (*b*). Even with frequent medium changes, these cultures could be kept at the monolayer stage for at least 2 weeks: neither cell death nor cell division could be detected by microscopic examination. The cells became larger and expanded on the plastic surface, a morphology reminiscent of that of the normal cells and different from that of wild-type polyoma virus transformants and of the same MTT cells in high serum medium. On addition of 10% calf serum, these cultures resumed their growth up to the high cell densities characteristic of transformed lines (data not shown). When serum was completely omitted, wild-type transformants could still grow, but MTT cells either grew very poorly or died over a period of 5–7 days (Fig. 2*c*). Below a critical serum concentration, cells which express only middle T thus have the growth properties on plastic of non-transformed cells. This also applies to their ability to divide in the absence of anchorage : all MTT lines tested so far exhibited a high cloning efficiency in agarose medium containing 10% serum (see also ref. 8), but, unlike cell lines transformed with wild-type viral DNA, none of them could form even microcolonies when the serum concentration was reduced to 0.5% (Table 3). This differential serum requirement of cells expressing only middle T has been confirmed without exception using other FR3T3-derived MTT lines, as well as middle-T-only lines derived from F2408 (see Table 3, ref. 28 and P. Kaplan and B. Ozanne, personal communication).

Table 2 Efficiency of transformation of FR3T3 rat cells and of rat embryo fibroblasts by plasmids encoding individual polyoma virus early proteins

	Foci per plate		
		Rat embryo fibroblasts	
Plasmid	FR3T3 cells	Expt 1	Expt 2
pBR322	0	0	0
pPY1	128	56	256
pPyLT1	0	0	NT*
pNG1	0	0	NT
pPyMT1	90	0	0
pPyST1	0	0	NT
pMC1	0	NT	NT
pLT214	0	0	NT

Confluent primary cultures, prepared as described in ref. 38 from 14-day-old Fischer rat embryos and parallel cultures of an early passage of the FR3T3 line[21] were seeded at a density of 2×10^5 cells per 35-mm Petri plate (Lux) in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% newborn calf serum (Gibco). After 24 h, the cells were fused with bacterial protoplasts (5×10^3 to 10^4 protoplasts per cell) of *E. coli* 1106 bacteria carrying the indicated plasmids, according to our previously published procedure[22]. Three days later, cells were trypsinized and plated at a density of 10^5 cells per 35-mm Petri plate. Cultures were stained with Giemsa and foci were counted after 10 days for FR3T3 cultures and after 1 month for rat embryo fibroblast cultures (no further increase in the number of foci was observed after 8 weeks incubation of parallel plates for both types of cultures). Numbers are total foci per 8×10^5 FR3T3 cells, 4×10^5 rat embryo cells in expt 1 and 2×10^6 in expt 2. NT, not tested.

Table 3 Growth in agarose medium of normal, wild-type polyoma-transformed and pPyMT1-transformed rat lines

	Colony-forming ability in agarose medium supplemented with:	
Cell line	10% Calf serum	0.5% Calf serum
FR3T3	<0.001	<0.001
PYT21	100	14
4.2	100	20
MTT1	100	<0.001
MTT4	100	<0.001
2.9	100	<0.001

10^5 cells of the indicated line were seeded in agarose medium supplemented with the indicated amount of serum. Microcolonies per microscope field were counted after either 8 days (10% serum) or 15 days (0.5% serum) and values were normalized as per cent of the cell input. The origin of cell lines MTT1, MTT4 and PYT21 is indicated in Fig. 2 legend. The same results were obtained for three other MIT lines independently isolated from FR3T3 (MTT2, MTT3, MTT5). Transformed lines 4.2 and 2.9 were derived[8] from F2408 Fischer rat established fibroblasts after transfection with plasmids containing either wild-type (4.2) or pPyMT1 polyoma (2.9) DNA.

Can serum-dependent MTT transformants be complemented by other viral proteins?

To assess whether the serum-dependent transformed phenotype of MTT transformants could be complemented by one of the other early viral proteins, MTT4 cells were fused with bacterial protoplasts carrying various plasmids, seeded in medium containing 0.5% serum and submitted to selection for stable transformants (Table 4). Colonies in agarose medium were observed, not only after transfer of a complete transforming region, but also with plasmids pNG1, pLT1, pMC1 and pLT214, that encode either a full-size or a truncated large T protein and cannot by themselves transform FR3T3 cells (see Tables 2, 5). Similar complementation results were obtained when focus formation at low serum concentration was used as the transformation assay (data not shown).

Several agar colonies and foci resulting from complementation were picked and grown into cell lines at low serum concentration. They all now had the growth properties characteristic of wild-type transformants. Representative cell lines, complemented with the pPyLT1 plasmid, were tested for the expression of the large T protein: unlike the parental MTT4 cells, they exhibited the nuclear staining by immunofluorescence with anti-T antigen serum characteristic of the large T protein (data not shown) and immunoprecipitation of T antigens demonstrated the expression of a full-size large T protein (Fig. 3*a*). A novel immunoprecipitable polypeptide could be detected in MTT cells complemented by DNA encoding only the N-terminal 40% of the large T polypeptide (plasmid pMC1, see Table 1) (Fig. 3*b*). Like the full-size large T protein, it could be labelled *in vivo* with ^{32}P-orthophosphate. Its apparent molecular weight (40,000) closely corresponds to the size predicted from the DNA sequence (36,700) and is identical to that of an immunoprecipitable polypeptide previously identified in a cell line (FR3T3-BR70, see below) isolated after transfer of lasmid pMC1 in FR3T3 cells[21]. Although further characterization of this protein is required, these results support the genetic evidence that the activity of a truncated large T protein can complement the serum dependence of MTT transformants.

No efficient complementation was observed in the progeny of MTT cells fused with pPyST1 protoplasts (Table 4). However, prolonged incubation of these plates produced a significant number of very small colonies in agarose medium, or foci on plastic plates. A representative number of these colonies were picked, but we have been unable to establish from these cells lines able to grow in low serum medium.

Selection of transformants at low serum concentration

The results described above suggested that pPyMT1 DNA alone was unable to transform FR3T3 cells if transformation were monitored by growth at low serum concentration[29]. We would further expect transformation in such conditions to be complementable by plasmids able to rescue the serum factor dependence of MTT transformants. In the experiment reported in Table 5, FR3T3 cells were fused to pairs of protoplasts carrying either pBR322 or pPyMT1 plus other viral recombinants or pBR322. Transformed colonies were quantified in agarose medium containing either 10 or 0.5% serum, and focus formation was measured in liquid medium containing 0.5% serum. The results confirmed both expectations. Transfer of pBR322 plus individual polyoma recombinants yielded transformation in 10% serum with genomic (pPY1) or middle T (pPyMT1) plasmids, but in 0.5% serum, only with the pPY1 genomic plasmid. Complementation of pPyMT1 transformation in 0.5% serum was clearly observed with the recombinant genomes that encode at least the amino-terminal 40% of the large T polypeptide (pPyLT1, pNG1, pMC1). Transfer of pPyMT1 plus the plasmid that encodes only the small T protein (pPyST1) did not yield visible foci in low serum medium, except after prolonged incubation (4 weeks) of the plates, where several very small foci were found. This effect of pPyST1, similar to that observed in the complementation of MTT cells (see above), also requires further study.

Selection for growth at low serum concentration in the absence of the middle T protein

Our complementation data showed that the characteristic very low requirements for serum growth factors of polyoma virus-transformed cells is under the genetic control of the large T gene. To test whether this phenotype can be acquired without expression of the middle T protein, selection for growth at low serum concentration was applied after transfer of the plasmids that code for the amino-terminal end of large T into cells of the highly serum-dependent FR3T3 line (see Fig. 2). FR3T3 cells, after transfer of vector DNA alone (Table 6), had a very low plating efficiency ($\sim 2\times10^{-3}$) in medium supplemented with 0.5% serum. This was increased by 5–10-fold (Table 6) when the cells had been fused with protoplasts carrying either pPyLT1 (or pNG1) or pLT214 (or pMC1). These clones could be further grown in low serum conditions into cell lines. In the presence of 10% serum, these lines had growth characteristics similar to those of the parental FR3T3 cells: they retained a low saturation density (Table 6) and did not grow in suspension. They could, however, be differentiated from the parental cells by their ability to grow to a low saturation density in the presence of 0.5% serum; curiously, the growth of such lines in low serum medium was similar to that of MTT lines in the same conditions (Table 6). Immunofluorescence measurements on representative lines derived after transfer of pPyLT1 showed positive nuclei characteristic of the expression of the large T protein. This is consistent with the conclusion that, at least after transfer of the entire large T gene, the modification in serum requirement results from the expression of a large T related polypeptide.

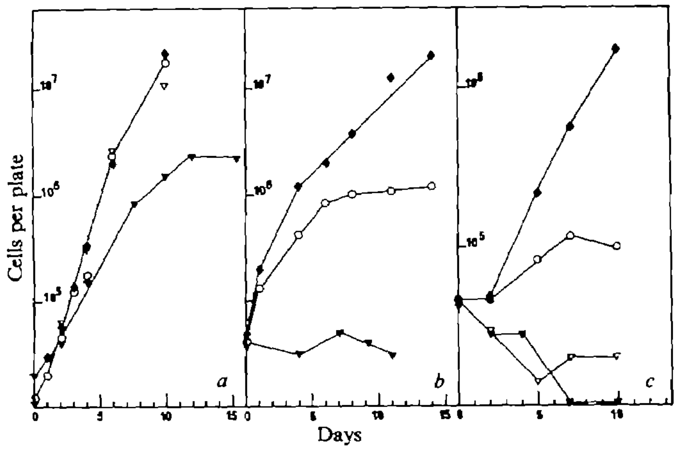

Fig. 2 Growth of normal FR3T3 cells and representative MTT and wild-type polyoma transformants at various serum concentrations. Cells were seeded at a density of 5×10^4 cells per 60-mm Petri plate in DMEM supplemented with either 10% (*a*) or 0.5% (*b*) serum or without addition of serum (*c*). The medium was changed every other day below 10^6 cells per plate and every day above this value. At the indicated times, plates were trypsinized and counted. MTT1 and MTT4 lines were derived from FR3T3 cells by focus formation in medium containing 10% serum after transfer of plasmid pPyMT1. PYT21 was established in a parallel experiment after transfer of plasmid pPY1. ▼: FR3T3; ◆: PYT21; ▽: MTT1; ○: MTT4.

Table 4 Complementation of MTT cells for growth in agarose medium at low serum concentration

Fusion of MTT4 cells with protoplasts carrying	Colonies per 10^5 cells 17 days	7 weeks
pBR322	0	0
pPY1	30	47
pPyMT1	0	0
pNG1	20	38
pPyLT1	8	32
pMC1	12	20
pPyST1	0	15*
Control without fusion	0	0

MTT4 cells were seeded (2×10^5 cells per 35-mm plate) in DMEM containing 0.5% serum. They were fused the next day with 10^4 protoplasts per cell of *E. coli* 1106 bacteria carrying the indicated plasmids. After 24 h, cells were trypsinized and seeded (10^5 cells per 60-mm plate) in agarose-gellified DMEM containing 0.5% newborn calf serum. Colonies were first counted after 17 days and again after 7 weeks. Numbers are averages of six plates.

* Minute colonies of slow-growing cells.

In an independent experiment[21], plasmid pMC1 (see Table 1) was transferred into FR3T3 cells and progeny colonies, grown in 10% serum, were randomly screened for the expression of a viral nuclear T antigen. Out of the 77 clones tested, 6 were weakly positive and one of them, FR3T3-BR70, was kept for further analysis. These cells were shown[21] to synthesize a protein immunoprecipitable with anti-polyoma virus T antigen, with the expected molecular weight of 40,000, identical to that of the antigenic protein now observed in MTT cells complemented by pMC1 plasmid (see above Fig. 3). The cells had the same morphology, growth inhibition in suspension and low saturation density (Table 6) as the original FR3T3 cells when studied in the presence of 10% serum. However, the results described above would imply that, unlike FR3T3, they should grow in medium supplemented with 0.5% serum. This prediction is confirmed by the data shown in Table 6, strongly suggesting that expression of the N-terminal portion of the large T protein is sufficient to reduce the growth factor requirement of FR3T3 cells.

DNAs separately encoding the early proteins do not transform primary embryo fibroblasts

We have thus far described experiments with FR3T3 rat cells which demonstrate an effect of the large T gene on cellular growth regulation: expression of the large T protein, or only its N-terminal region, confers on both parental and middle T-transformed FR3T3 cells a reduced dependence on serum growth factors. To test the more general significance of our findings, we decided to investigate the requirements for transformation of non-clonal fibroblast cultures derived from primary explants of rat embryos ('primary' cells). Polyoma virus is known to be able to transform primary rodent cells. In addition to the transformation characters observed in transformed derivatives from established normal cell lines, it was recognized that virus transformation enables the cells to grow in culture for an unlimited period[30]. When plasmids containing wild-type or modified viral genomes were transferred into primary rat fibroblasts, transformation resulted only with the wild-type DNA (Table 2). Plasmid pPyMT1, encoding only the middle T protein and active in parallel experiments in the transformation of FR3T3 cells, did not transform primary cells, even in medium containing 10% serum. Experiments are in progress to determine whether the pairwise transfer of early genes would transform these cells.

Concluding remarks

We have confirmed previous evidence that the middle T protein alone can confer on established cell lines a phenotype similar to that of wild-type polyoma-transformed cells. Expression of this protein, however, was not sufficient to maintain the transformed state in low serum growth conditions in the highly serum factor-dependent line FR3T3. The low serum growth defect of FR3T3 lines expressing only the middle T protein could be complemented with equivalent efficiencies by DNA encoding either all or no more than the N-terminal 40% (334 amino acids) of the large T protein. Similarly, co-transfer of DNA encoding either the full-size large T protein or only its N-terminal region complemented the ability of the middle T gene to transform FR3T3 cells in low serum medium, yielding transformants which were not dependent on exogenous growth factors for expression of the transformed phenotype. Transfer of the full-size or truncated large T gene alone was sufficient to promote growth of normal FR3T3 cells at low serum concentrations, but did not induce expression of other properties (lack of topoinhibition, anchorage independence) characteristic of transformation. We therefore conclude that the middle T and large T gene products have independent effects on cellular physiology which together are responsible for the phenotype of wild-type transformants.

An important motivation for the collaborative efforts reported here was to resolve the apparent discrepancy between the observation that middle T expression alone was sufficient to transform established rat cells of the F2408 line[8] and reports that at least the N-terminal region of the large T gene was additionally essential to maintain the transformed state in lines derived from FR3T3 by infection with the *tsa* mutant of polyoma virus[21]. We found that cell lines derived from FR3T3 after transfer of the pPyMT1 plasmid conditionally express the transformed phenotype in a manner dependent on growth factor concentration. The same DNAs which were able to complement *tsa* transformants for transformation at the restrictive temperature were shown to complement the serum-dependent defect of cell lines expressing only middle T. Thus, the present experiments confirm the original suggestion[31] that the large T protein, or only its N-terminal region, plays an important part in the maintenance of transformation.

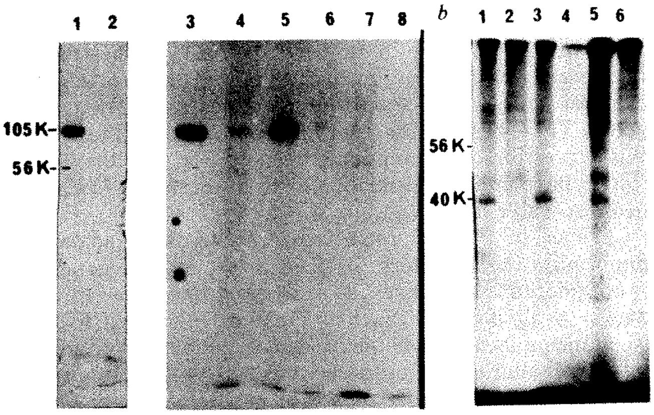

Fig. 3 Immunoprecipitation analysis of the viral proteins synthesized in cells derived from MTT transformants by complementation with the full-size or truncated large T genes. Cell lines MLT1 and MLT2 were independently derived from MTT4 cells after transfer of plasmid pPyLT1, and cell lines MMC1, MMC2 and MMC3, from MTT4 cells after transfer of plasmid pMC1 (see Table 1), by selection for colonies grown in agarose medium in the presence of 0.5% serum. Cells were subcloned twice in succession and routinely maintained in DMEM containing 0.5% serum. Before labelling, the cells were seeded at a density of 10^5 cells per 10-cm Petri plate and grown for 4 days in the presence of 10% serum. Labelling was for 2 h in the presence of 250 μCi of ^{32}P-orthophosphate (Amersham France) in 1 ml of Tris-buffered isotonic saline solution. Extracts were prepared and analysed by immunoprecipitation with anti-polyoma T antigen immune serum as described in ref. 21. Concentration of polyacrylamide was 10% for the gel shown in *a*, and 12.5% for that in *b*. The indicated electrophoretic mobilities corresponding to apparent molecular weights of 105,000, 56,000 and 40,000 were deduced from the position of protein markers on the same gels[21]. *a*: lane 1, MLT2 cells, immune serum; lane 2, MLT2 cells, control serum; lane 3, MLT1 cells, immune serum; lane 4, MLT1 cells, control serum; lane 5, PYT21 cells, immune serum; lane 6, PYT21 cells, control serum; lane 7, MTT4 cells, immune serum; lane 8, MTT4 cells, control serum. *b*: lane 1, MCC3 cells, immune serum; lane 2, MCC3 cells, control serum; lane 3, MCC2 cells, immune serum; lane 4, MCC2 cells, control serum; lane 5, MCC1 cells, immune serum; lane 6, MCC1 cells, control serum.

Table 5 Transformation frequencies after co-transfer into FR3T3 cells of polyoma sequences encoding different early proteins

Bacterial protoplasts carrying:	Transformants per 10^5 cells in DMEM supplemented with: 10% Calf serum Foci	Agar	0.5% Calf serum Foci
pBR322	0	0	0
pBR322 + pPY1	95	48	65
pBR322 + pNG1	0	0	0
pBR322 + pPyLT1	0	0	0
pBR322 + pMC1	0	0	0
pBR322 + pPyMT1	74	37	0
pBR322 + pPyST1	0	0	0
pPYMT1 + pNG1	79	16	31
pPYMT1 + pPyLT1	NT	15	39
pPYMT1 + pMC1	46	14	22
pPYMT1 + pPyST1	60	27	0*

FR3T3 cells (2×10^5 cells per 35-mm plate) were fused either with 2×10^9 protoplasts of *E. coli* 1106 carrying pBR322 or with the same total number of protoplasts prepared from mixed cultures (50:50) carrying the indicated plasmids. After 24 h, two plates from each group were trypsinized and the cells were seeded in four plates, two in liquid medium and two in agarose medium, in DMEM supplemented with 10% calf serum. Four days later, two more plates from each group were transferred into two 10-cm plates in medium supplemented with 0.5% serum. Foci and agar colonies were counted at day 16. Numbers are means of two plates (10% serum) or four plates (0.5% serum).

* Minute foci of slow-growing cells were observed after prolonged incubation of the plates (4 weeks).

We still, however, cannot explain why FR3T3 cells after transfer of the middle T gene have only a serum-dependent conditional defect in transformation, whereas *tsa* virus transformed cells of the N type revert to a normal phenotype at 40 °C in the presence of 10% serum[31]. We recently transferred into MTT FR3T3 cells a viral genome encoding only large T and carrying the *tsa* mutation (M.R. and F.C., unpublished experiments). These cells display a serum-dependent transformed phenotype at 40 °C but not at 33 °C. This result provides further important evidence for the continuous requirement for a large T gene product to maintain transformation in low serum medium, but differs from that obtained with *tsa*-transformed cells. The difference may result from the establishment of the transformed lines in recent experiments by DNA-mediated transfer of a large number of gene copies per cell, rather than by virus infection at low input multiplicities[31] in the former study. Also, the *tsa* transformants were established at the permissive temperature, in the presence of an active large T protein. A role for this protein in the formation of the head-to-tail tandemly integrated viral genomes commonly observed in virus transformants was indicated by recent experiments using *tsa* mutants[32]. Another approach is suggested by results obtained with temperature-dependent SV40 *tsa* transformants[33] indicating that these cells behave as transformed cells at 40 °C in the presence of 20% serum, but not with only 10%

Table 6 Derivation of cell lines with reduced serum requirement by selection in medium containing 0.5% calf serum after transfer into FR3T3 cells of large T coding genes

a, Plating efficiency of FR3T3 cells after transfer of plasmids encoding large T

Plasmid	No. of colonies 5×10^3 Cells per plate	 10^4 Cells per plate
pBR322	10	28
pPyLT1	80	150
pNG1	100	NT
pLT214	60	132
pMC1	89	160

b, Growth of FR3T3 cells and of FR3T3 derivatives selected after transfer of genes encoding large T

Cell line	Relative cell growth in DMEM containing: 10% Serum (day 8)	 0.5% Serum (day 8)	 (day 15)
FR3T3	60	1	1
PYT21	800	70	400
FR3T3–BR70	110	9	41
FR3T3–LT1	100	12	38
MTT4	800	14	40

a, FR3T3 cells were fused with protoplasts carrying the indicated plasmids as described in Table 2 legend. After 24 h, the cells were trypsinized and replated at the indicated densities in 10-cm Petri plates in medium supplemented with 0.5% serum. Giemsa staining and colony counting were done 1 month later. In these conditions, the efficiency of cloning of the FR3T3 cell line in DMEM containing 10% newborn calf serum is of the order of 50%. *b*, FR3T3–BR70 cell line was derived from FR3T3 cells after transfer of plasmid pMC1 (ref. 19, and see text) and FR3T3-LT1, after transfer of plasmid pPyLT1 by selection of clones in medium containing 0.5% serum (*a*). Cells were seeded at day 0 at a density of $1–5\times10^4$ cells per 60-mm Petri plate, depending on the line, in medium containing the indicated concentration of serum. Cells of parallel cultures were trypsinized and counted at days 0, 8 and 15. Values shown are ratios of cell number at the indicated time to that at day 0. Values underlined correspond to confluent arrested monolayers. These cultures resumed their growth after trypsinization and seeding at lower density in the same medium.

serum. Both polyoma *tsa* and MTT lines could thus in fact be serum-dependent transformants, the critical serum concentration being higher for the *tsa* lines than for MTT cells. Experiments are in progress to test these hypotheses.

Our present data suggest that the region of the large T protein involved in the alteration of cell growth control is localized within its amino-terminal 334 residues. This genetically defined domain would retain its biological activity after deletion of other parts of the polypeptide chain, as previously demonstrated for various multifunctional proteins, such as *Escherichia coli* DNA polymerase I[34]. Experiments using available mutants[35] are in progress to localize more precisely this functional domain. It may be encoded by the segment of genomic DNA with two open reading frames that also encodes the C-terminal half of the middle T protein (see Fig. 1). Deletions within this region of the genome are already known to affect tranformation[35]. Are the two functions of polyoma virus which cause oncogenic transformation encoded by alternative reading frames in a single DNA sequence?

We further show here that DNA encoding only the middle T protein does not stably transform rat embryo fibroblasts. We suspect that transformation of primary cells also requires a function exerted by the large T protein, that would confer on cells an unlimited growth potential in culture ('immortalization' function). Recent experiments demonstrated that transfer of DNA encoding only large T into primary rat embryo cells allows the establishment of permanent cell lines which do not express other transformation characters; these lines, as one might predict, could be efficiently transformed by plasmid pPyMT1 DNA (ref. 10 and M.R., Z. Naghashfar, N.G., R.K. and F.C., manuscript in preparation). This function of the large T gene may be related to its ability to reduce the serum requirement of established cell lines because it is also retained by the genes encoding only the N-terminal part of the protein.

Responsiveness to growth factors, modulated by the large T protein, may thus appear as critical both in the expression of oncogenicity and in the acquisition by primary cells of an unlimited growth potential in culture. Further biochemical investigations should define the nature of the growth factors involved. Recent experiments on cell lines expressing only the middle T protein (ref. 28 and B. Ozanne, personal communication) indicate that these cells secrete in the culture medium growth factor(s) that transiently induce the expression of a transformed phenotype in normal cells. Cells synthesizing the other viral polypeptides, including large T, secrete elevated levels of such factor(s) and are more responsive to growth factors. These observations may account for the fact that FR3T3 cells expressing only the middle T protein or only the large T protein have indistinguishable growth properties in low serum medium (Table 6).

Changes in the cell requirement for growth factors and immortalization in culture, induced by the large T gene, may be considered from our results as an early step in the transformation of rat fibroblasts. Such observations might help to establish at the molecular level the concept of neoplastic progression by 'graded alterations', proposed long ago by Rous (see ref. 36 for review) and originally applied to papova virus transformation by Vogt and Dulbecco[30].

We thank L. Carbone, F. Tillier and M. L. Varani for technical assistance. Biohazards associated with the experiments performed in France have been examined previously by the French National Committee and experiments were carried out according to the rules established by this committee.

Making ends meet: a model for RNA splicing in fungal mitochondria

On the basis of available nucleotide sequence and genetic data, we present a model for RNA splicing in fungal mitochondria. Seven intron RNAs of two fungal species can form identical secondary structures, involving four conserved sequences, which bring the ends of each intron together and allow an internal guide RNA sequence to pair with exon bases adjacent to the splice junctions. The splicing sites are thus aligned precisely within a conserved structure, which we suggest could present specific recognition signals to the proteins that catalyse the splicing reaction.

MANY eukaryotic genes are interrupted by DNA sequences which do not code for any part of the gene product. These DNA sequences are known as introns (or intervening sequences), whereas the coding regions of the gene are called exons. Introns have been found in eukaryotic mRNA, tRNA and rRNA nuclear genes, and also in mitochondrial mRNA and rRNA genes of fungi[1-3] and at least one plant mitochondrial mRNA gene[4]. In all cases introns are transcribed as part of the primary RNA transcript and are then excised by 'splicing'—a precise cleavage and ligation reaction which leaves the various exons joined together end to end in their order of synthesis. The mechanism of splicing has not been fully elucidated for any intron. We now present a model which shows how the RNA of one class of mitochondrial intron could take up a well defined secondary structure, allowing the precise and unambiguous alignment of the ends of exons flanking the intron ready for the cleavage and ligation reactions. We have used two lines of evidence in constructing the model. Comparison of the DNA sequences of four mitochondrial introns of *Aspergillus nidulans* which we recently determined (ref. 5 and R.B.W. *et al.*, in preparation) and five of *Saccharomyces cerevisiae*[6-8] highlights certain key conserved sections of intron sequence. When these are taken as the basis of the formation of base-paired regions of the RNA molecule, further conserved RNA–RNA pairing between non-conserved sequences is revealed, and quite remarkably all these introns can form very similar RNA secondary structures. Genetic evidence, provided largely by the work of Slonimski and co-workers[9-12], shows that particular short segments of the intron sequence distant from the splicing sites are important in *cis* for splicing; our model explains the phenotypes resulting from *cis*-acting mutations.

The introns studied are listed in Table 1 and the terminology used is described in Fig. 1 legend. The sequences that are highly conserved in introns of both species[5] are named P, Q, R and S; their sequences and locations are given in Table 1. Seven of the introns have the internal primary structure shown in Fig. 1[9,13]: a *cis*-acting region occupies the 5′ end of the intron (which in mRNA introns has an open reading frame), a central protein-coding region extends from just beyond conserved sequence R to the stop codon and there is a 3′ *cis*-acting region with no open reading frame. The protein-coding region of YC4 has been shown[9,13] to code for a protein essential for the excision of YC4 ('mRNA maturase')[11], and this is probably the case for several other introns. The general features of the model will

The nucleotide sequences and locations within nine fungal mitochondrial introns of regions that are important for RNA splicing, including the conserved sequences P, Q, R and S, are shown. The latter are named in their order of occurrence in the 5′ to 3′ direction within the introns. The E, E′ and IG sequences are described in the text. Numbers indicate distances in bases between particular sequences. The asterisk marks the conserved G base of the IGS. P and Q are the same as A and B, respectively, in ref. 5.

0028–0836/82/510719—06$01.00

be presented first, followed by a detailed consideration of the supporting evidence.

A model of mitochondrial RNA splicing

Figure 2 gives a diagrammatic representation of the steps in the splicing process, and Fig. 3 shows the actual secondary structure of the folded intron RNA. The model proposes three major stages in the excision of these introns.

(1) Intron RNA forms a specific secondary, and presumably tertiary, structure involving a number (usually nine) of conserved RNA–RNA interactions, with the result that the ends of the intron are brought close together. The RNA–RNA pairings involving the conserved sequences P, Q, R and S are among the most critical. The P and Q sequences are synthesized early, and their pairing P4 and the associated P5 (Fig. 3) are important in nucleating the secondary structure. The R–S pairing P7 and the associated P8 (Fig. 3) bring the 3′ end of the intron close to R, which is in turn brought close to the 5′ end of the intron by the pairing of the E and E′ sequences. Proteins may also be involved, binding at specific sites on the intron RNA either to stabilize secondary structure or to aid the formation of the precise alignment structure in stage 2. We regard the characteristic secondary structure formed by pairings P3 to P9 in Fig. 3 as the 'core structure' of these introns. The formation of the core structure is a prerequisite for the next stage.

(2) An internal guide sequence (IGS) located just 5′ to the E sequence (Figs 1, 3) pairs with short stretches of RNA sequence at the end of the upstream exon and the beginning of the downstream exon, acting as an adaptor molecule that brings the two splicing sites tightly together, separated only by the length of a phosphodiester bond. The IGS–upstream exon pairing is P1 in Fig. 3, the IGS–downstream exon pairing is P10. The P1 and P10 pairings involving IGS make up the precise alignment structure, details of which are given in Fig. 6 for nine introns. In all cases the splice sites are precisely aligned, and are in similar chemical environments at the ends of symmetrically placed helices. As shown in Fig. 2, this structure also ensures that exon–exon ligation is favoured, because when the RNA is cut at the exon–intron junction the exon ends are held in the double-stranded region, while the intron ends are free to diffuse away.

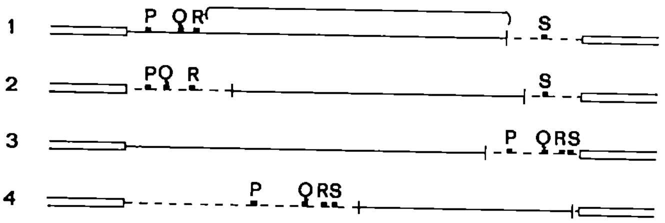

Fig. 1 A schematic representation of the internal primary structure of a class of fungal mitochondrial introns. Four different arrangements of open reading frames are shown; class 1 is the majority arrangement, found in six of the nine introns discussed here, while the other classes have one representative each. Internal features of each intron are shown to scale, but all introns have been scaled to the size of the class 1 intron. Symbols are as follows: open bars, exon sequences; continuous line, open reading frame within an intron; discontinuous line, intron sequence with no open reading frame. The bracketing line above the class 1 intron indicates the part of the yeast cob I4 intron in which *trans*-acting mutations of the *box*7 class have previously been located; this defines the maturase coding region. P, Q, R and S are the conserved sequences shown in Table 1. The results presented in this article are based on the comparison of nine intron DNA sequences, four from *A. nidulans* and five from yeast. We refer to these and other introns by species, gene and number only, symbolizing *S. cerevisiae* by Y and *A. nidulans* as N, and dropping 'intron'. Thus, yeast introns are written as follows: cob I3, YC3; cob I4, YC4; oxi3 I3, YOX3; oxi3 I4, YOX4; 21S rRNAω, Yω. *A. nidulans* introns are written as follows: cobA I1, NC; oxiA I1, NOX1; oxiA I2, NOX2; oxiA I3, NOX3. The data for Yω (ref. 8), YC4 (ref. 7), YOX3 and YOX4 (ref. 6) have been published, and those for NC, NOX1, NOX2 and NOX3 are from our laboratory and will be published in detail elsewhere (ref. 5 and R.B.W. *et al.*, in preparation). Nine introns NC, NOX1, NOX2, NOX3, YC3, YC4, YOX3, YOX4 and Yω, have been studied but we only show analyses based on eight of the introns plus those portions of the YC3 sequence that have already been published[21]. In this figure intron 1 = YC4 (YOX4, YC3, NC, NOX2 and NOX3 are similar to YC4), 2 = Yω, 3 = YOX3 and 4 = NOX1.

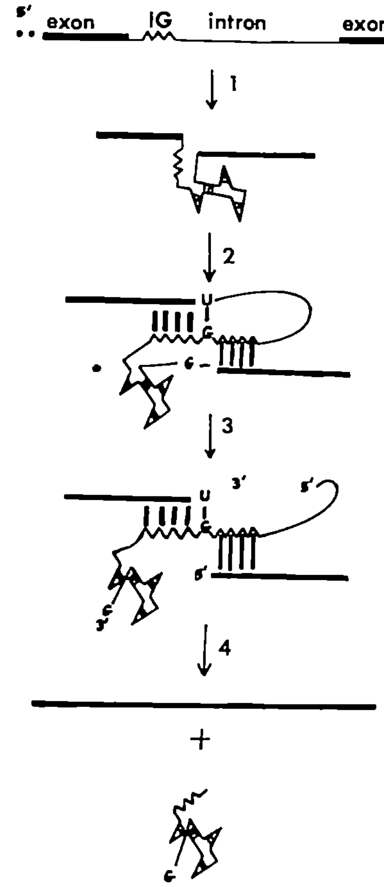

Fig. 2 Model of the role of the RNA substrate in mitochondrial RNA splicing. The model is described in the text. The steps shown here are: (1) formation of internal secondary structure; (2) formation of the precise alignment structure; (3) endonuclease binding followed by specific cuts to produce the ends shown and diffusion of free intron ends away from the splicing complex; (4) ligation of exon ends and release of linear intron RNA from the splicing complex. The precise alignment complex which is P1 + P10 of Fig. 3, is shown greatly enlarged between stages (2) and (4). The thick line represents exon RNA, the thin line intron RNA, the zigzag line the internal guide RNA sequence (IGS).

(3) The completed precise alignment structure is recognized by the splicing protein(s). The features recognized are the RNA structure *per se*, and certain chemical groups that only occur together near the splice sites in the complete structure, in particular the U · G base pair (bp) of P1 adjacent to the 5′ splice site and the G base at the 3′ end of the intron. In addition, the protein(s) recognizing this structure may also need to bind to components of the core structure or its associated proteins so as to bind efficiently. The specificity of the reaction is dictated by other non-conserved chemical signals and by the mRNA maturase[13]. Endonucleolytic scission at the 5′ and 3′ splice sites may be simultaneous or sequential. The free ends of intron RNA diffuse away immediately but the free ends of exon RNA are still held in the P1 and P10 pairings, and are ligated together by an RNA ligase which need not be specific. The splicing proteins are released from the IGS; the P1 and P10 pairings fall apart, releasing the linear intron (which is presumably subsequently destroyed) and the spliced mRNA.

The core structure

The fact that all introns considered here possess the same core secondary structure argues for the functional importance of this structure. This is strongly supported by our ability to explain the phenotype of all the sequenced *cis*-acting mutations affecting splicing, and by the maintenance of intact base-pairing despite variations from the consensus sequences. We stress that if any one intron RNA sequence is considered alone it is possible to find alternative ways of pairing the conserved sequences, but the model secondary structure presented in Fig. 3 is applicable to all the introns of both species. We have only considered pairings to be potentially biologically meaningful if they occur between identical or identically placed sequences of all the introns studied.

The extreme regularity and conservation of detail of RNA secondary structure within introns can be seen in Fig. 3*a*; all the conserved bases shown in the core structure in this figure are present in at least six out of eight introns and the conserved base pairs in all or seven out of eight introns. One of the most remarkable features that these introns have in common is the existence of a pair of sequences named by us E and E′ (Table 1, Fig. 3). Two bases after the conserved sequence R, there is a conserved G base in all the introns followed by a C base in five out of seven introns. These two bases together with the next four (three in YC4, five in YOX4 and Yω) make up the sequence we call E′. The amazing property of E′ is that, although the last four bases are completely different from intron to intron, they and the GC preceding them are always capable of pairing perfectly with a sequence E that precedes sequence P by three bases (Figs 3, 6). This conservation of precise base-pairing ability of sequences in identical positions in all introns, independent of actual nucleotide sequence conservation, demands the interpretation that these sequences really do pair.

Further evidence for the functional importance of the RNA–RNA interactions between P and Q, R and S is provided by looking at the effects on the pairings of variations from the consensus sequence. Sequences P and Q are strongly conserved between introns and species, but there are several variations from the consensus sequences. In all cases where a different nucleotide sequence is found within the section of P that can pair with Q, a compensatory alteration in sequence Q is found so that the base-pairing between the sequences is maintained. There are five such compensatory exchanges, the most striking being the case of NOX1, where an insertion of a base in P is exactly compensated for by two changes in Q. There are no alterations in the proposed base-pairing region of P that are not compensated for by complementary alterations in Q. The pairing regions of the R and S sequences are very precisely conserved; only in NOX3 does a change occur in part of the R sequence that pairs with S, and here too a compensatory alteration in S is found. All these compensatory exchanges in the variant sequences are shown in Fig. 4.

This model also accounts for the phenotypes due to several *cis*-acting mutations affecting splicing which have been sequenced by Slonimski and co-workers[9,12]. The mutations fall into two clusters, which in YC4 have been called *box*9 and *box*2. All the *box*9 mutations that have been sequenced (including the equivalent class in YOX4) fall in R or E′, and reduce the strength of base-pairing either of R and S or of E and E′; as R and E′ are separated by only one base, they have previously been considered to be part of one functional sequence, whereas we propose that they have different roles, although both are involved in secondary structure formation. Details of the sequenced mutations are given in refs 9 and 12, and their effects on the R–S and E–E′ interactions are shown in Fig. 5. Two mutations of the *box*2 class which affect sequence S of YC4 have also been sequenced[9]. Both W300-3 and G2590 alter G (ref. 8) to A; this would destroy a central G · C base pair in the pairing of S with R (Fig. 5). Thus, our proposal also explains the observed phenotype of *box*2 mutations. Weakening of the R–S or E–E′ pairings by these mutations will reduce the stability of the core structure, thus preventing efficient

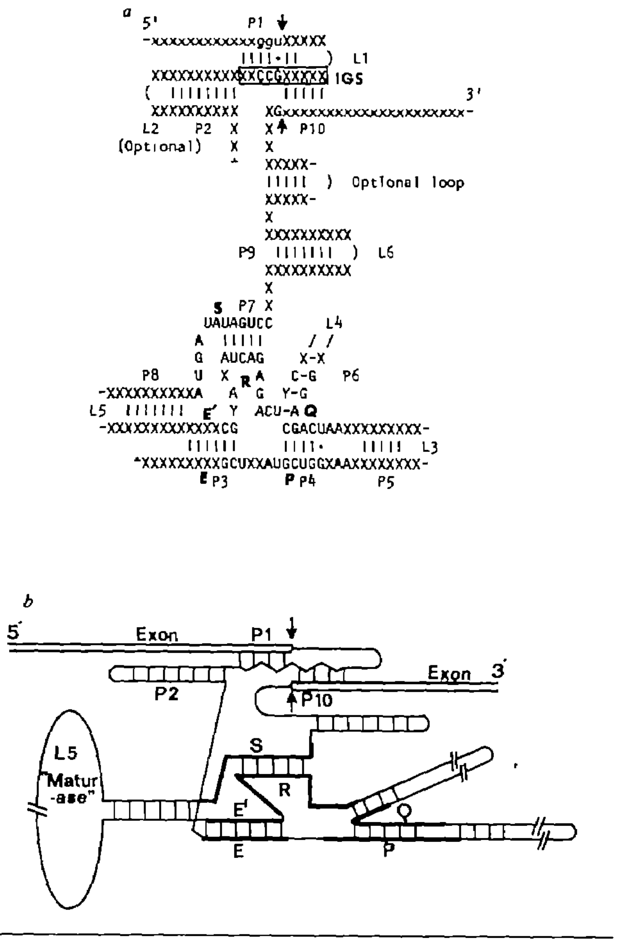

Fig. 3 Model RNA secondary structure for a class of fungal mitochondrial introns. *a*, A generalized secondary structure model derived from the RNA sequence of eight introns (YC3 data were not used), showing conserved bases and conserved pairings between non-conserved bases. *b*, A diagrammatic representation of the secondary structure showing only the key components. For convenience of two-dimensional representation, the RNA structure has been shown in *a* as if cut between P2 and P3 (or just 5′ to E)—the arbitrary ends that are left are marked with an asterisk and the sequence is continuous between these points. Intron bases are in capitals, exon bases in lower-case letters. A, U, C or G is written when these bases occur in a particular position in at least six out of eight introns, while Y indicates a pyrimidine and R a purine base in six out of eight introns; otherwise X or x signifies any base. Except for P1 and P10 (see Fig. 6) when a base pair is given, it occurs in at least seven out of eight introns in this position. When the end of a stem–loop structure is closed by a round bracket, the number of bases shown is that of the consensus intron; when the end is shown with a dash after each nucleotide, then a large variable number of bases is found in the loop (see Table 1). Base-paired regions are labelled P1 to P10, loops L1 to L6. L5 contains the maturase-coding region of the majority class intron; the putative maturase-coding region of YOX3 occurs in L1, and this loop is also large (though non-coding) in NOX1. YOX3 and NOX1 have small L5 loops, all others have small L1 loops of the average size shown in the consensus structure. P3 is formed by the pairing of P and Q, P7 by the pairing of R and S, P1 and P10 by the pairing of IGS with exon sequences. The central core of the structure is P3, P4 and P7 with the associated P5, P6 and P8. P2 and P9 are peripheral stems which bring the splice sites close to the folded central core; P1 and P10 form the precise alignment structure. In *b* exons are shown as open bars, conserved sequences as thick solid lines, IGS as a wavy line, and base pairs are shown where conserved. The line joining P2 to E is of necessity out of scale, and represents only four bases on average. The L5 loop is shown as coding for the maturase protein as in YC4, but it can code for non-maturase protein (Yω), be defective for protein coding (YOX4, NOX3), or very small (NOX1, NOX3).

formation of the precise alignment structure. This is why mutations within an intron cause splicing defects.

No mutations have so far been isolated in P, Q or E. This is probably because the genetic map is not saturated, that is, only a small proportion of all the possible mutations affecting splicing have been identified. Most of the mutations that have been isolated in R, S and E' are leaky[13], so if point mutations in P and Q had slightly weaker effects they could be difficult to detect. Alternatively, the mutations that have been isolated may affect not only RNA–RNA pairing but also alter the specific binding sites of proteins involved in splicing, and the P–Q pairing might not bind any protein at all. The model predicts that the distribution of small deletion mutations would be much more widespread and include P and Q, that point mutations will be found in E, and that E mutations will be found as suppressors of E' mutations and vice versa.

The precise-alignment structure and the internal guide sequence

At some stage of splicing the splice sites must be aligned precisely and held together long enough for the excision of the intron and the ligation of at least the exon ends to be achieved. Although this could conceivably be done by proteins alone, a very reliable and precise way of aligning two nucleotide sequences is by way of complementary base-pairing with an adaptor molecule[14,15]. We propose that this class of fungal mitochondrial intron RNAs possesses an internal guide sequence that functions as an adaptor, pairing with upstream and downstream exon sequences adjacent to the splice sites in such a way as to place the splice sites together exactly. The base-pairing in this precise-alignment structure need not be very extensive because we propose that the previous folding of the RNA core structure strongly favours the pairing of the internal guide sequence with the exon RNA sequences. In fact, most of the precise-alignment structures shown in Fig. 6 involve base-pairings (P1, 3–6 bp; P10, 3–8 bp) that are comparable with those proposed for the pairing of the U1 external guide RNA with intron sequences in the alignment of the ends of nuclear mRNA introns[14,15] without previous folding.

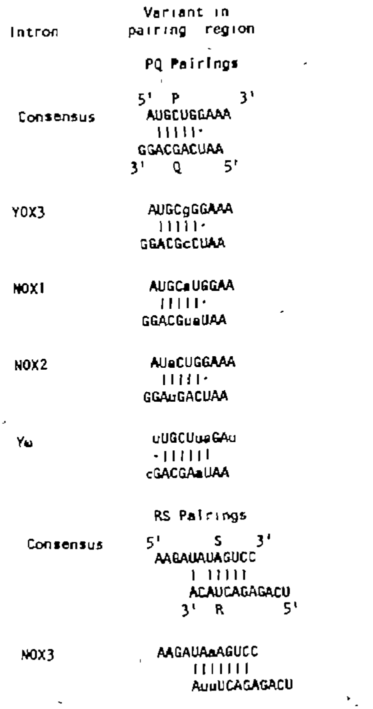

Fig. 4 The P–Q and R–S pairings with variants. Consensus pairings and all known exceptions are shown, demonstrating the conservation of base-pairing in the variant introns. Bases that differ from consensus are shown in lower-case, consensus bases in capitals. Intron terminology is given in Fig. 1 legend.

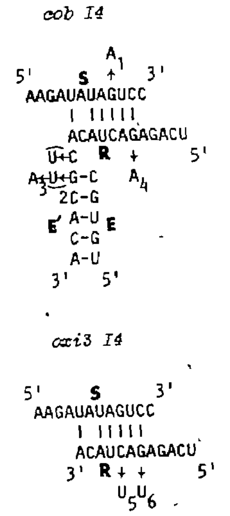

Fig. 5 Mutational evidence for the R–S and E–E' pairings. The R–S pairing of YOX4 and the R–S and E–E' pairings of YC4 are shown with all the sequenced *cis*-acting mutations affecting splicing[9,12]. Numbers next to bases in mutants indicate the identity of the mutant[9,12,13]: 1 = G2590 and W300-3; 2 = M4474 (a double base change); 3 = M7832; 4 = V353; 5 = G2190; 6 = G192.

The internal guide sequences are given in Table 1, and the IGS–exon pairings making up the precise-alignment structures are shown in Fig. 6; these correspond to P1 and P10 of Fig. 3. A similar though slightly shifted version of an alignment structure was proposed for Yω by Bos *et al.*[16]. If P1 is considered in isolation it involves an extra 1 or 2 bp beyond the U · G pair shown as the end of P1 in Fig. 6; these base-pairings are between the first bases of the intron and one or two of the IGS bases that can also take part in the P10 pairing.

The first argument in favour of this structure is the regularity with which it can be formed by a sequence (IGS) between the 5' splice site and sequence E. There are several conserved features, which can be located in Fig. 3 and seen in detail in Fig. 6. The finding that the precise-alignment structures are variable apart from these features agrees well with the considerable specificity of splicing reactions; note that the alignment structures and IGS of YOX4 and YC4, which share the same splicing specificity[13], are very similar.

The phenotypes resulting from two known mutations can be explained if the mutations reduce the strength of the pairings in the precise-alignment structure. G2457 is a mit$^-$ mutation of yeast that is clearly defective in the excision of YC4, but has been shown by DNA sequencing to be a single G → A transition affecting the last but one nucleotide of the upstream exon[9]; this G → A change would significantly reduce the stability of the pairing, as well as affecting the potential protein-binding site. This G and its pairing with a C in IGS within the P1 pairing are strongly conserved. The other example is the class of mutations known as ω^n, which occur in the gene for the large mitochondrial rRNA of *S. cerevisiae*; ω^n mutations remove the strong polarity (biased transmission of parental genotypes to offspring) that is otherwise found in crosses between ω^+ and ω^- strains of *S. cerevisiae*. ω^+ and ω^- strains differ in the presence and absence of the Yω intron, and ω^n mutations only occur in ω^- strains, never in ω^+ strains. ω^n mutations have been shown by DNA sequencing[8] to be a G → A transition three bases before the end of the upstream exon. This would reduce the strength of the P1 pairing in our model. Clearly, if this prevents RNA splicing, ω^n mutations could never occur in ω^+ strains because the Yω intron would not be excised and this would be lethal.

The proposed structure thus fulfils all the criteria for a structure having a critical role in determining the precision of the splicing reaction. As for P, Q and E, we expect mutations to be found in the IGS and further mutations to be found in the exon sequences near splice junctions as the genetic map becomes saturated.

Two introns which definitely have the core structure but only weak precise-alignment structures differ from the seven other introns in having extra DNA present between at least one splice junction and the core structure sequences (Fig. 1). The core structure of these introns is still necessary (hence its conservation) but not sufficient for bringing the ends of the intron together. There are two ways of interpreting the structure of NOX1 and YOX3. First, these introns are now spliced in a different way from the other seven, and either a completely new recognition mechanism has been superimposed or intron excision occurs in multiple steps, one of which may correspond to the standard model. Second, they are still spliced in the standard way, the extra DNA contributing additional secondary structure to correct for its own presence.

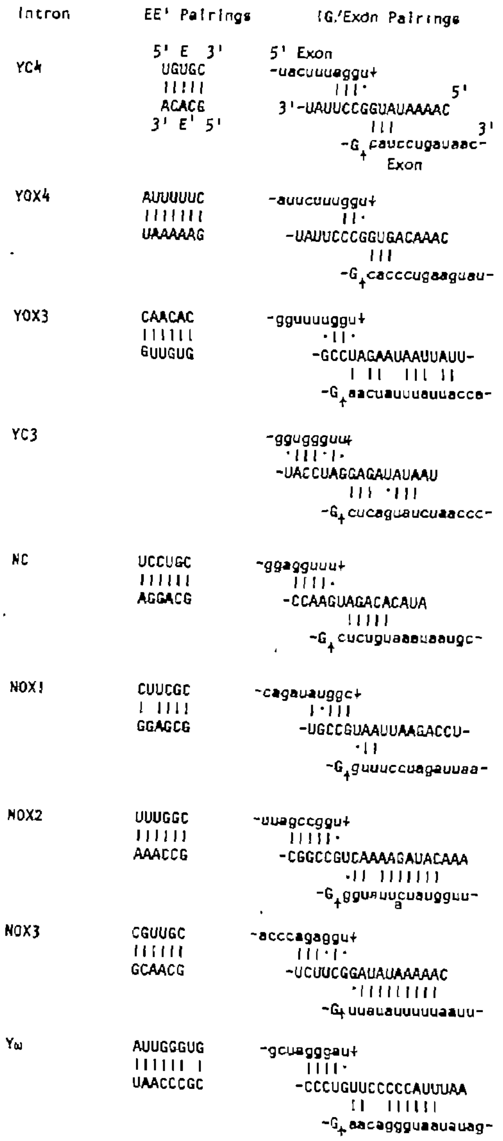

Fig. 6 Base pairing between the internal guide sequences and exon sequences adjacent to the 5′ and 3′ splice sites, and base pairing between E and E′ in nine fungal mitochondrial introns. Intron bases are in capitals, exon bases in lower-case lettering. The precise alignment structures are shown for convenience as if both the 5′ and 3′ cuts have been made. The intron bases that were in the L1 loop (Fig. 3*a*) are shown as a linear array in the middle line with the first (5′) base of the intron on the right, except where a dash indicates that a large number of bases are present 5′ to the sequence shown. Arrows indicate the cut sites. The last (3′) base of the intron is shown to the left of the 3′ cut site because this G is a conserved feature of the precise alignment structure. The one or two IGS bases that can pair either in P1 or P10 (Fig. 3*a*) are thus shown in their P10 pairing mode.

Proteins and the splicing reaction

The model deals with the role of RNA sequences in the splicing process, and not with the role of proteins or the mechanism of the reaction itself. It demonstrates, however, that proteins are probably involved in stabilizing RNA secondary structure as well as in the cutting and ligation steps. Splicing proteins may also need to recognize parts of the secondary structure instead of, or as well as, sequences near the splice junctions.

The form of the precise-alignment structure has consequences for the mechanism of the splicing reaction. IGS bases have two alternative pairings as shown in Fig. 3*a*. Once the core structure, perhaps aided by proteins, allows the P10 pairings to form, the two forms of the structure must exist in an equilibrium due to branch migration unless one is favoured by the local environment. If the fully formed P10 pairing is present for a reasonable fraction of the time, or is stabilized by proteins, then simultaneous cuts could be made at the 5′ and 3′ cut sites in a structure which has both the cut sites at the junction of a very short (half-turn) helical segment with single-stranded RNA, and separated only by the length of a phosphodiester bond.

It is important to make the two cuts spatially and temporally close together so as to reduce the error rate of the reaction, and this can be achieved if recognition and cutting of the 5′ and 3′ ends only occur efficiently once the whole structure has formed. Given this proviso, a sequential mechanism is possible with a nick first occurring at the 5′ scission site in the top strand of the full P1 pairing of Fig. 3*a*; the last base pair or two of P1 then dissociate or are displaced by P10 branch migration, and the 3′ cut is made. Even a fully sequential mechanism is possible if P1 is stabilized by proteins after the 5′ cut has been made. In certain nuclear mutant[17] and *cis*-acting mutant[18] strains of yeast, the 5′ cut can occasionally be made independently of the 3′ cut.

A strong body of evidence[13] supports the involvement of intron-coded mRNA maturases in the excision of some of these introns. These could be important at any stage in the splicing process, including the endonuclease reaction. One specific problem of mitochondrial RNA splicing is that RNA synthesis and splicing and protein synthesis occur in the same compartment in mitochondria, so that the RNA being spliced is simultaneously being translated. The hypothesis that ribosomes have a positive role in splicing[9,13] has received a little experimental support[19]. Ribosomes are likely to disrupt any secondary structure that does form, and in most of these introns ribosomes must cross the 5′ splice junctions to synthesize the maturase. A positive role for ribosomes within the framework of our model might be to inhibit premature 5′-end cutting by disrupting the P1 pairing, although there are alternative ways of achieving this. However, ribosomes travelling into the intron will tend to disrupt the core structure. We have assumed that ribosomes are sufficiently well spaced to allow the splicing complex to form (ribosomes within loops should have little effect). If ribosomes are closely spaced, one of the roles of proteins binding to the core structure may be to prevent the disruption of the structure by ribosomes. In this case it is possible that the maturase is involved in stabilizing the structure against disruption by ribosomes, as well as acting as at least a specificity factor in the splicing reaction.

Conclusions

The class of fungal mitochondrial introns which we have considered possess, according to our proposal, all the specific elements required for their own excision. The model presented here accounts for all the data at present pertaining to the precise excision of these introns, and makes clear predictions of classes of mutations that should be found as well as suggesting the possible types of activity of proteins involved in splicing. In this model there can also be no ambiguity in the splicing of multiple introns within one RNA precursor molecule, as the dependence of the formation of the splicing complex on previous folding of the intron RNA ensures that the 5′ and 3′ ends of the same intron are always chosen for the excision reaction.

This mechanism of RNA splicing may be of more general importance, because at least one nuclear intron, that in the gene for the large nuclear rRNA of *Tetrahymena*, fits this model precisely (R.B.W. *et al.*, in preparation).

We thank Drs J. Lazowska and P. P. Slonimski for communicating some of their data on YC3 before publication, and Dr B. Dujon for pointing out that Yω had certain features of this class of intron. We acknowledge the help of many workers in the field, but particularly Professor Slonimski and his group whose precise genetic analysis of mitochondrial RNA splicing provided essential evidence. This work was supported by MRC Hproject grant G7904290CB to R.W.D. and C.S.

Note added in proof: One prediction of the model has already been fulfilled: Dr P. S. Perlman and co-workers (personal communication) have obtained a mutation in E that blocks splicing of YC4. Dr R. Schweyen and co-workers (personal communication) have obtained the same base change in E as a revertant of a *box*9 mutation in E′, and the double mutant has regained an intact pairing region. Computer-aided analysis of intron RNAs of *S. cerevisiae* and *Kluyveromyces thermotolerans*[20] has provided RNA structures in excellent agreement with the consensus core structure presented here.

Characterization of a regulatory region upstream of the *ADR2* locus of *S. cerevisiae*

David R. Beier & Elton T. Young

Department of Biochemistry SJ-70, University of Washington, Seattle, Washington 98195, USA

We have used in vitro *mutagenesis to identify a DNA sequence that is required for glucose regulation of the* ADR2 *locus of* Saccharomyces cerevisiae. *This region, located between 200 and 1,000 base pairs upstream of the structural gene for ADH II, has been identified by genetic and biochemical analysis as the site of* ADR3, *a* cis-*acting regulatory locus. If this region is deleted,* ADR2 *is no longer repressed by glucose. Moreover, if the sequence is excised and ligated in front of the* ADC1 *gene, it puts that gene under glucose control.*

THE eukaryotic promoter has been identified by site-specific mutagenesis and deletion analysis of cloned genes[1–6]. In several cases it has been possible to identify regions which have regulatory functions[7–10], and occasionally, DNA sequences immediately 5′ to the transcription initiation site have been implicated in regulating the expression of the adjacent structural gene. In other cases regulatory DNA sequences have been identified at a considerable distance from the affected gene[11–14].

We have chosen to examine the regulatory regions which affect the expression of the alcohol dehydrogenase (ADH) isozymes of the yeast, *Saccharomyces cerevisiae*. The 'classical' ADH I is synthesized during fermentative growth and is repressed about fivefold during growth on ethanol-containing medium[15]. A second isozyme, ADH II, is repressed when yeast are grown on glucose and is derepressed 100-fold when yeast are grown on a nonfermentable carbon source[16]. The structural genes coding for both ADH I (*ADC1*) and ADH II (*ADR2*) have been identified genetically[18], cloned[19,20] and their DNA sequences determined[21,22].

We show here that deletion of a specific 5′-flanking sequence of *ADR2* results in the loss of glucose control of ADH II synthesis. This sequence overlaps *ADR3*, a genetically defined *cis*-acting locus which regulates *ADR2*[23]. In addition, we show that these sequences can be removed from their normal context in front of *ADR2*, placed upstream from the promoter of a different gene (*ADC1* in this case), and still retain their function.

Construction of an *ADR2* deletion

There is extensive nucleotide sequence homology in the region between the TATAA boxes and the transcription initiation sites of *ADC1* and *ADR2*[22]. The presence of an *Sph*I restriction site immediately 5′ to this homologous region in *ADR2* allowed us to test the hypothesis that regulatory sequences would be 5′ to the *ADR2* TATAA box. If this idea were correct, a deletion of sequences 5′ to the *Sph*I site would prevent glucose repression of *ADR2*. To minimize gene dosage effects, the *ADR2* gene constructs were inserted into pBC3T1, a stable, single-copy vector containing a yeast centromere from chromosome 3 (*CEN3*)[24] and the *TRP1* gene[17] (see Fig. 1). A 2.6-kilobase (kb) *Bam*HI/*Sph*I fragment containing *ADR2* and 1.2 kb of 5′-flanking sequence was cloned into pBC3T1 and designated pADR2. A second DNA fragment containing *ADR2* and only 176 base pairs (bp) of 5′ sequence was inserted into the *Sph*I site of pBC3T1. Clones with the fragment inserted in both orientations [pADR2(−176)R and pADR2(−176)L] were isolated.

These plasmids were used to transform the trp$^-$ yeast strain 302-21 which contains defective alleles of all three ADH structural genes: *adc1-11*, *adr2-43* and *adm* (the last gene codes for a minor ADH isozyme found in the mitochondria). Single TRP$^+$ colonies were isolated and grown on medium containing either glucose or ethanol. Cell extracts were prepared and assayed for ADH enzyme activity. As the results given in Table

0028-0836/82/510724—05$01 00

Table 1 ADH enzyme activities of transformed yeast cells

	Plasmid	ADH activity (mU per mg) Glucose	ADH activity (mU per mg) Ethanol
I	pADR2	30	1600
	pADR2(-176)L	1200	2000
	pADR2(-176)R	1100	4100
II	pADR3/ADC1(-414)	10	300
	pADC1(-2000)	2200	1300
	pADC1(-414)	4300	8300
III	pADR3/ADC1(-220)	10	200
	pADR3/ADC1(-150)	30	900
IV	pADR3/ADC1(-1400)	2000	1300
	pADC1(-1400)	2300	1100

The trp$^-$ yeast strain 302-21 was transformed with plasmid DNA according to the method of Beggs[29]. TRP$^+$ colonies were selected at random and assayed for enzyme activity in repression and derepression conditions using the following protocol. Cells from a stationary culture were inoculated into 10 ml trp$^-$ minimal media containing 8% glucose at a concentration of $\sim 5\times10^5$ cells per ml. These cultures were grown overnight at 30 °C to a concentration of $\sim 2\times10^7$ cells per ml. One half of the culture was collected and assayed, the remaining half was washed once in H_2O and resuspended in 5 ml trp$^-$ minimal media containing 3% ethanol. These cultures were grown for another 24 h at 30 °C and then collected. Assays were performed according to the method of Lutsdorf and Megnet[16]. Each value represents the average of the enzyme activities measured for three to five independent transformants.

1, section I, show, enzyme activity in strain 302-21 transformed with pADR2 is repressed on glucose-containing medium and derepressed on ethanol-containing medium. The amount of enzyme activity present in derepressed cells is comparable to that found for a strain containing a functional chromosomal *ADR2* gene (Table 2, strain 43-2B). Transformants of strain 302-21 containing an *ADR2* gene deleted to 176 bp 5′ to the structural gene [pADR2(−176)L and pADR2(−176)R] have high levels of ADH (>1,000 mU per mg protein) even on glucose-containing medium. This is true for the fragment cloned in either orientation with respect to the vector, thus arguing against the likelihood that the expression observed is due to transcription initiated at a vector site with readthrough of the *ADR2* gene. This result strongly implies that the region that has been deleted in the plasmids pADR2(−176)R and pADR2(−176)L (that is, the region 5′ to an *Sph*I site 176 bp upstream of the structural gene) contains sequences which are required for catabolite repression of *ADR2*.

Construction of an *ADR3/ADC1* hybrid

The identification of an *Sph*I site at −414 bp in the 5′-flanking region of *ADC1* allowed a further test of the hypothesis that the 5′ *Bam*HI/*Sph*I fragment of *ADR2*, which we will designate *ADR3*, contains regulatory sequences. If this region is essential for catabolite repression, ligation of the *Bam*HI/*Sph*I fragment in front of *ADC1* should confer glucose repressibility on ADH I. The *Bam*HI/*Sph*I fragment was ligated to an *Sph*I/*Bam*HI fragment containing *ADC1*, and the hybrid was cloned into the *Bam*HI site of pBC3T1 and designated pADR3/ADC1(−414). To compare the expression of this hybrid gene with that of *ADC1* containing its own 5′-flanking sequences, two other plasmids were also constructed. A 3.5-kb fragment containing *ADC1* and 2,000 bp of 5′-flanking sequence was cloned into pBC3T1, and designated pADC1(−2000). An *Sph*I fragment containing *ADC1* and only 414 bp of 5′-flanking sequence was cloned in the same vector. This construction, pADC1(−414), was tested to ensure that a deletion of sequences 5′ to −414 bp (the *Sph*I site) did not affect ADH I synthesis.

ADH activity was measured in cell extracts prepared from strain 302-21 transformed with the plasmids just described. Insertion of the *ADR3* sequence 5′ to the *ADC1* gene [pADR3/ADC1(−414)] dramatically reduces ADH activity when cells containing the plasmid are grown on glucose-containing medium (Table 1, section II). The enzyme activity increases after growth in derepressing conditions to about 20% of the value obtained in extracts of cells transformed with pADR2. Strain 302-21 transformed with either pADC1(−2000) or pADC1(−414) has abundant enzyme activity when grown on either glucose- or ethanol-containing medium. The enzyme activities found for pADC1(−2000) are comparable to values found in strains with a functional chromosomal *ADC1* gene. These results show that the repression observed with the hybrid gene, pADR3/ADC1(−414), is due to the *Bam*HI/*Sph*I fragment normally flanking *ADR2*.

To identify which ADH isozyme is expressed in these transformed strains, cell lysates were analysed by electrophoresis on a non-denaturing polyacrylamide gel and stained for ADH activity (Fig. 2). Only ADH II is detected in cell extracts prepared from yeast transformed with pADR2 and the plasmids containing deletions 5′ to ADR2. However, the isozyme present in cell extracts prepared from the strain transformed with the hybrid pADR3/ADC1(−414) is the *ADC1* gene product, ADH I. This proves that the repression and derepression of ADactivity that occur in cells transformed with the hybrid plasmid is not due to the inadvertent isolation of a transformed strain containing wild-type *ADR2*.

Construction of hybrids using *ADC1* 5′ deletions

Derepression of *ADC1* in the hybrid construction pADR3/pADC1(−414) is weak compared with that observed for pADR2. The efficiency of derepression might be influenced by the distance of the *ADR3* sequence from the promoter.

Table 2 ADH expression in strains containing regulatory mutations that affect *ADR2*

	ADH activity (mU per mg)							
	Strain 526-3 (*ADR2 ccr1*)		302-21 (*adr2 ADR1*)		SF6-4A-M4 (*adr2 ADR1-5^c*)		500-16 (*ADR2 adr1*)	
Plasmid	Glc	EtOH	Glc	EtOH	Glc	EtOH	Glc	EtOH
pADR2	20	47	30	1,600	360	5,600	47	1,100
pADR3/ADC1(−414)	NT	NT	10	300	43	1,400	30	2,500
pADR3/ADC1(−150)	9	15	30	900	170	3,100	8	1,300
pBC3T1 (vector)	1	10	3	11	7	10	2	16
	Strain: 526-3 (*ADR2 ccr1*)		43-2B (*ADR2 ADR1*)		R234 (*ADR2 ADR1-5^c*)		500-16 (*ADR2 adr1*)	
	Glc	EtOH	Glc	EtOH	Glc	EtOH	Glc	EtOH
Genomic *ADR2*	1	10	15	1,850	414	5.400	1	7

The enzyme activities of strains 43-2B and R234 are according to Ciriacy[25] All other activities were measured as described in Table 1 legend. NT, not tested.

Therefore, *ADC1* clones with deletions 3′ to the *Sph*I site were constructed and tested for their ability to express ADH I. Compared with a cloned *ADC1* gene with 2,000 bp of 5′-upstream sequence [pADC1(−2000)], deletion of 5′-flanking sequence to within 150 bp of the beginning of the structural gene has no effect on the level of *ADC1* expression when yeast containing these plasmids are grown on glucose-containing medium (results not shown).

The result that deletions of yeast DNA between 414 and 150 bp 5′ to the *ADC1* gene did not reduce *ADC1* expression enabled us to test the hypothesis that *ADR3* function in a hybrid construction is sensitive to its position relative to the *ADC1* promoter. The *Bam*HI/*Sph*I fragment (*ADR3*) was ligated closer to *ADC1* using the 5′-deleted plasmids pADC1(−220) and pADC1(−150), which are deleted to within 220 and 150 bp 5′ to *ADC1*, respectively. These hybrid gene constructions are designated pADR3/ADC1(−220) and pADR3/ADC1(−150).

These plasmids were used to transform strain 302-21; the transformed colonies were tested for enzyme activity and the results are shown in Table 1, section III. Ligation of the *ADR3* sequences 100 bp 5′ to the TATAA homology region (pADR3/ADC1(−220)) resulted in no increase of derepressed enzyme activity relative to the original hybrid construction. However, strain 302-21 transformed with pADR3/ADC1(−150), in which this sequence is only 30 bp 5′ to the TATAA homology region, has threefold higher ADH activity. The enzyme activity is ~60% of that found in the strain containing the cloned *ADR2* gene, pADR2.

These results demonstrate that the efficacy of the *ADR2* operator, *ADR3*, for the promotion of transcription of the adjacent gene during derepression depends on its placement with respect to the promoter of that gene. To test this idea further, a hybrid gene was constructed such that the *ADR3* region was located far upstream (~1,300 bp) from the TATAA sequence of *ADC1*. This plasmid [pADR3/ADC1(−1400)] and a control plasmid containing only *ADC1* sequence [pADC1(−1400)] were used to transform strain 302-21.

The enzyme activities of cell extracts of tranformants are shown in Table 1, section IV. The activities found for yeast containing either pADC1(−1400) or pADR3/ADC1(−1400) are nearly identical to those found for yeast containing pADC1(−2000) when the cells are grown in either repression or derepression conditions. It seems that the *ADR3* sequence exerts no effect on *ADC1* expression when it is ligated at a site 1,300 bp upstream from the *ADC1* promoter. However, it is possible that sequences upstream of *ADC1* in this construction interfere with repression.

Glucose control of *ADR2* and *ADR3/ADC1* in mutant backgrounds

Strain 526-3 (*adc1-11, ADR1, ADR2, ccr1*) fails to express ADH II enzyme activity when grown on ethanol-containing medium due to a mutation at the regulatory locus, *CCR1* (ref. 25). This strain was transformed with the plasmids pADR2 and pADR3/ADC1(−150), and the ADH activity in the transformants measured (Table 2). Extracts of strain 526-3 containing these plasmids did not contain significant ADH activity when cells were grown on ethanol-containing medium. Therefore, *CCR1* function is required for derepression of enzyme synthesis for both pADR2 and pADR3/ADC1(−150).

ADR1 is another unlinked regulatory locus which affects *ADR2* expression. The semi-dominant *ADR1-5*^{c} mutation has two effects: it results in partially constitutive ADH II synthesis, and the ADH II activity is increased to a level higher than is found in *ADR1* wild-type cells during derepression[25]. A strain containing the *ADR1-5*^{c} mutation, SF6-4A-M4 (*adc1-11, adr2-43, adm*), was transformed with pADR2 and hybrids pADR3/ADC1(−414) and pADR3/ADC1(−150). The enzyme activities of extracts from the transformed strains are given in Table 2. The enzyme activities shown for pADR2 correspond to those found in a strain containing a functional chromosomal copy of *ADR2* (Table 2, strain R234). The enzyme activities of cells transformed with the hybrid plasmids pADR3/ADC(−414) and pADR3/ADC1(−150) are significantly elevated for both repressing and derepressing growth conditions relative to the levels found in a host strain containing wild-type *ADR1*. Again, the enzyme activities found in yeast containing pADR3/ADC1(−150) are higher than in

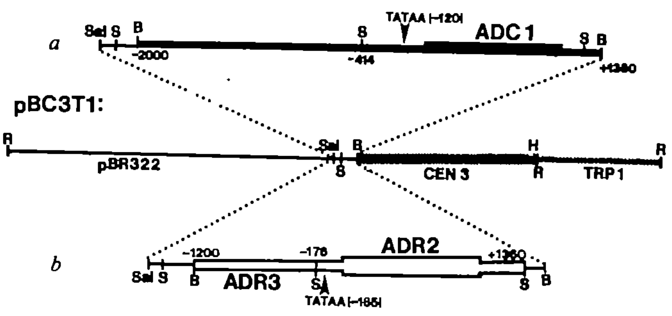

Fig. 1 Restriction map of vector pBC3T1 and yeast sequence inserts for pADC1(−2000) (*a*) and pADR2 (*b*). The vector pBC3T1 was constructed by first ligating a *Hin*dIII/*Bam*HI fragment containing the yeast centromere *CEN3*[24] into the *Hin*dIII and *Bam*HI sites of pBR322. Restriction enzymes and T4 DNA ligase (BRL) were used according to manufacturers' instructions Methods for preparative isolation of DNA fragments have been described elsewhere[20]. Plasmids from *E. coli* transformed to ampicillin resistance were analysed after extraction according to a method described by Holmes and Quigly[30]. The yeast *TRP1* gene was isolated from the yeast–*Escherichia coli* shuttle vector YRp7 by *Eco*RI digestion and ligated into the *Eco*RI site of the *CEN3*-pBR322 vector after treatment of the *Eco*RI-cut plasmid with calf intestine alkaline phosphatase (Boehringer). The orientation of the *TRP1* gene in pBC3T1 is the opposite of its orientation with respect to pBR322 sequences in YRp7. Plasmid pADR2 was constructed using a *Sal*I/*Sph*I fragment from YRp7–ADR2–BSb which contains a 2.7-kb insert of yeast sequences containing the *ADR2* structural gene[20]. This plasmid was digested with *Sal*I and partially with *Sph*I. A fragment containing 2.6 bp of yeast sequence including *ADR2* and 1,200 bp of 5′-flanking sequence was ligated into PBC3T1 cut with *Sal*I and *Sph*I. This construction has a direct repeat of ~200 bp of pBR322 sequences, which flank the yeast insert Plasmid pADC1(−2000) was constructed by isolating a 3.5-kb *Bam*HI fragment containing *ADC1* and 2,000 bp of 5′-flanking sequence from YRp9T6[19]. This was inserted into the *Bam*HI site of pBC3T1. To construct pADR2(−176)L, in which yeast sequences 5′ to the *ADR2 Sph*I site at −176 are deleted, plasmid pADR2(−1700) was partially digested with *Sph*I and religated. Plasmids in which the upstream sequences were deleted were identified by restriction digestion. To prepare pADR2(−176)R, which is a plasmid containing a deleted *ADR2* fragment cloned in the opposite orientation as pADR2(−176)L, an *Sph*I fragment containing the *ADR2* gene and 176 bp of 5′-flanking sequence was isolated. This fragment was cloned into pBC3T1 that had been cut with *Sph*I and treated with calf intestine alkaline phosphatase. The orientation of the inserted fragment was determined by restriction enzyme analysis. The plasmic pADC1(−414), in which the sequences 5′ to the *Sph*I site at −414 are deleted, was constructed in a similar manner to that described for pADR2(−176)L. A series of hybrid genes were constructed in which the *ADR3* regulatory region was ligated to a variety of sites 5′ to the *ADC1* gene and cloned in pBC3T1. Plasmid pADC(−414), with a deletion to the *Sph*I site at −414 of *ADC1*, was reconstructed to form a hybrid gene (pADR3/ADC1(−414)) by replacing the *Bam*HI/*Sph*I fragment upstream of *ADC1* with the 1-kb *Bam*HI/*Sph*I *ADR3* regulatory region. The plasmid pADR3/ADC1(−150) was constructed using an *ADC1* gene isolated from pADC1(−150), which contains a *Sal*I site ~150 bp 5′ to the *ADC1* structural gene. An *ADR3* fragment was prepared from a construction in which the *Sph*I site had been altered to a *Xho*I site using molecular recombination linkers (Collaborative Research). The 1-kb *Bam*HI/*Xho*I *ADR3* region and the *Sal*I/*Bam*HI *ADC1* fragment were ligated into pBC3T1 cut with *Bam*HI and treated with calf intestine alkaline phosphatase. Isolates in which the orientation of the structural gene with respect to the vector was the same as in pADC1(−2000) were identified by restriction analysis. The hybrid-gene plasmid pADR3/ADC1(−220) was constructed in the same manner, using *Sal*I/*Bam*HI fragment from pADC1(−220) in which a *Sal*I site is 220 bp 5′ to *ADC1*. The same method was used for the construction of pADR3/ADC1(−1400) using an *ADC1* fragment from a construction in which a *Hin*dII site, 1,400 bp 5′ to the structural gene had been converted to a *Xho*I site using molecular recombination linkers. This fragment was also used to construct pADC1(−1400), by cloning it into pBC3T1 cut with *Sal*I and *Bam*HI. Restriction enzyme cleavage sites are *Bam*HI (B), *Sph*I (S), *Sal*I (Sal), *Eco*RI (R) and *Hin*dIII (H).

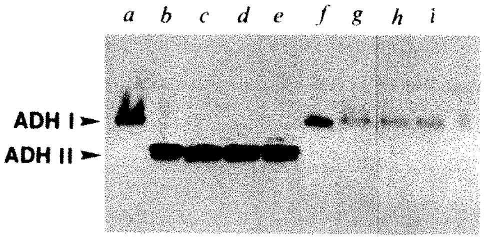

Fig. 2 Identification of the ADH isozyme expressed in transformed yeast cells. Cell extracts were electrophoresed on a non-denaturing polyacrylamide gel as previously described[19], and stained for ADH activity[28]. Lane *a* contains an extract from strain SF4-1B, which expresses only ADH I. Lane *b* contains an extract from strain R112, which expresses only ADH II. Lanes *c–i* contain extracts of strain 302-21 transformed with the following plasmids: *c*, pADR2; *d*, pADR2(−176)R; *e*, pADR2(−176)L; *f*, pADC1(−2000); *g*, pADR3/ADC1(−414); *h*, pADR3/ADC1(−220); *i*, pADR3/ADC1(−150).

yeast containing pADR3/ADC1(−414), in which the *ADR3* region is displaced further upstream relative to the *ADC1* promoter.

The recessive *adr1-1* mutation results in a very low level of *ADR2* derepression when cells are grown on ethanol-containing medium[23]. The plasmids described above were used to transform strain 500-16, which is defective for *ADR1 (adr1-1, adc1-11, ADR2, adm)*. Table 2 gives the ADH activities of these transformed strains and reveals the surprising result that the *ADR2* gene on a plasmid is abundantly expressed in derepressing conditions despite being in a host strain in which the chromosomal copy of *ADR2* is not expressed due to the *ADR1* defect. The hybrid pADR3/ADC1 plasmids also express ADH activity in abundance. In this case, pADR3/ADC1(−414) is more fully derepressed than in a wild-type *ADR1* background.

Analysis of cell extracts by electrophoresis detected only ADH I activity in the pADR3/ADC1 transformants, proving that the chromosomal copy of *ADR2* is not derepressed concomitantly with the plasmid genes. Independence of *ADR1* is not due to the absence of upstream control sequences in pADR2, as three multi-copy plasmids containing the *ADR2* gene with 1, 6 and 13 kb of 5′-flanking sequence are all derepressed in a strain containing the defective *adr1-1* allele (results not shown).

Discussion

Two different lines of evidence suggest that the promoter for transcription of *ADR2* can be separated from its operator region, *ADR3*. First, deletion of yeast sequences upstream from an *Sph*I site 176 bp 5′ to the coding region of *ADR2* allows constitutive synthesis of ADH II on glucose. Second, when these upstream sequences are ligated to *ADC1*, this gene becomes glucose repressible. Because the presumed TATAA box for *ADR2* transcription is located 160 bp 5′ to the coding region of *ADR2*, we conclude that all the sequences essential for efficient transcription of *ADR2* are located between the TATAA box and the initiation site of transcription, which is 54 bp 5′ to the coding region of *ADR2*.

The operator region, defined as the DNA sequences which can confer glucose repressibility on either *ADR2* or *ADC1*, extends upstream from approximately position −176 for not more than 1 kb. This same region overlaps the *ADR3* locus which was identified by *cis*-acting regulatory mutations that allow partially constitutive ADH II synthesis on glucose medium[23]. Most of these *ADR3*^{c} mutations are caused by Ty insertions between positions −210 and −125[26]. Two non-Ty induced *ADR3*^{c} mutations have been located by cloning and DNA sequence analysis at position −220 (D. Russell, personal communication). Thus, there is a good correspondence between the genetic locus, *ADR3*, and the DNA fragment that confers glucose repressibility.

The function of the *ADR3* region depends on its position with respect to the promoter of the adjacent gene. Glucose repression mediated by *ADR3* is effective when the fragment is as far as 300 bp upstream from the TATAA box of *ADC1*. In contrast, efficient derepression of the hybrid gene occurs only when *ADR3* is ligated within 30 bp of the promoter. The evidence that hybrid genes can be constructed in which derepression of *ADC1* is incomplete but repression is apparently normal suggests that repression and derepression might occur by independent mechanisms.

The repression and derepression conferred by the *ADR3* locus contained on plasmids is subject to some of the same regulation as is the chromosomal *ADR3* region. Derepression of the hybrid gene pADR3/ADC1(−150) requires *CCR1* function. *CCR1* is a pleiotropic effector which is required for the derepression of several glucose-repressed enzymes, including *ADR2*[25]. The hybrid gene also shows appropriate response (that is, increased enzyme activity) to *ADR1-5*^{c}, a regulatory mutation that results in partially constitutive synthesis of ADH II[25]. However, plasmids containing *ADR3* do not require *ADR1* for expression of the neighbouring structural gene (either *ADC1* or *ADR2*) as does the chromosomal *ADR2* locus. This result is not understood.

The identification of glucose control sequences for *ADR2* and the effect of operator–promoter separation on gene activity may help explain how transposable elements alter *ADR2* expression. The ADH II-constitutive phenotype resulting from Ty insertion may be a consequence of the displacement of the operator far enough upstream of the promoter to negate its effect, as proposed previously[26,27]. This hypothesis is consistent with the failure of *ADR3* to show any control over *ADC1* when it is ligated 1,300 bp upstream from its promoter, as in pADR3/ADC1(−1400). Secondary mutants of Ty-insertion *ADR2* mutants in which the Ty element has been replaced by a single 340-bp delta sequence have negligible ADH II activity when grown on glucose-containing medium and are only weakly derepressed[27]. In these mutants the position of *ADR3* with respect to the TATAA sequence is similar to that found in the hybrid pADR3/ADC1(−414). Cells transformed with this hybrid also have enzyme activities that are low when grown in either repression or derepression conditions.

We thank Clyde Denis, Valerie Williamson and Andrzej Sledziewski for useful discussions, and Richard Palmiter and John Osterman for reading the manuscript. *CEN3* was kindly provided by John Carbon. D.B. is a predoctoral student in the University of Washington Medical Scientist Training Program (GM 07266). Financial support for this research was provided by NIH grant GM-26079.

A new class of radio pulsars

M. A. Alpar*, A. F. Cheng†, M. A. Ruderman* & J. Shaham*‡

Sufficiently low magnetic field neutron stars which accrete for long times from a surrounding keplerian disk can be spun up to millisecond periods. After accretion ceases, such stars could become isolated or binary pulsars, depending on whether their companions have subsequently disrupted the binary by either their tidal break ups or their supernova explosions. Such pulsars constitute a new class, with short periods, long apparent ages ($P/\dot{P} \gtrsim 10^8$ yr) and pulsed optical, X-ray and γ-ray fluxes significantly below those expected for canonical pulsars with similar periods. Because of their long subsequent spin-down lifetimes, such pulsars would probably be observable if their birth rate exceeded even 10^{-4} that of the canonical ones. We propose here that the recently discovered millisecond pulsar 4C21.53 belongs to this new class, together with the binaries PSRs 1913+16, 0820+02 and 0655+64, as well as possibly several isolated pulsars such as PSRs 1952+29 and 1804−08. The possibility of such a class of fast accretion-spun-up pulsars has also been noted by Backus *et al.*[1].

Several kinds of observations support the view that many neutron stars in the close accreting binaries which constitute the galactic bulge X-ray sources have weak ($B \ll 10^{11}$ G) surface magnetic fields: (1) analyses of post-burst cooling of X-ray bursters imply that accretion has been effective over the entire neutron star surface with no important effects from magnetic funnelling to polar regions[2–5]; (2) in such neutron stars there is no sign of the modulation of X-ray emission expected from rotation of a magnetized stellar surface with $B \gg 10^{10}$ G (ref. 6); (3) good agreement with theoretical models for burst properties is achieved when magnetic funnelling is not effective ($B < 3\times10^{11}$ G)[7]. In addition, various scenarios which would be expected occasionally to lead to such binaries imply some very low field neutron stars[8]. Thus, for an accreting 'non-magnetic' white dwarf[9] ($B < 10^5$ G) which grows beyond the Chandrasekhar limit and collapses to a neutron star, simple flux conservation alone would be expected to amplify B to at most 10^9 G. Finally, theoretical models offer various reasons for expecting strong reductions in (dipolar) magnetic fields in many or most old ($\gg 10^7$ yr) neutron stars which cause them to be extinguished as pulsars[10,11].

There are a variety of scenarios for systems in which a neutron star accretes from a keplerian accretion disk initially fed by a companion[8,12]. First, low mass X-ray binaries (galactic bulge sources). Typical accretion rates are 10^{-9}–$10^{-10}\,M_\odot\,\text{yr}^{-1}$ for 10^9–10^{10} yr so that a mass $\gtrsim 10^{-1} M_\odot$ is transferred to the neutron star. Because of orbit shrinking due to gravitational radiation[12] the ultimate fate of such binaries must be a single neutron star or black hole. The low mass primary, even if it became a white dwarf first, will ultimately overflow its diminishing Roche lobe and be partly accreted onto the neutron star with the remainder dispersed in space. In some cases the accreting neutron star may become massive enough to collapse to a black hole, but often the remainder should be an isolated neutron star, embedded in the dilute remnant cloud of that part of the companion which was not accreted. For circular low mass binaries this last stage of evolution will take $<10^{10}$ yr if the initial binary period is of the order of 5 h or less[13]. For highly elliptical orbits such as that of the binary pulsar PSR 1913+16 this can be accomplished with longer initial periods. (We note that even a double neutron star binary such as PSR 1913+16 must ultimately end as a single rapidly spinning neutron star or black hole.)

Second, high mass X-ray binaries where mass transfer is very rapid ($\sim 10^4$ yr) into the Roche lobe of the neutron star. Much of this mass may ultimately form a keplerian disk before accretion onto the neutron star. The primary may then evolve to a supernova which disrupts the binary or leaves behind a bound collapsed companion. Neutron star accretion from a relatively massive partially filled Roche lobe may well continue long after the primary has disappeared if the Eddington limit rather than disk viscosity is controlling the accretion.

When the accretion region nearest to the neutron star is a keplerian disk the star will spin up until the keplerian angular velocity at the disk inner edge (the stellar magnetosphere's Alfvén radius) approximately equals that of the star. When enough matter is accreted to achieve this steady state, the equilibrium period[12,14,15] is

$$P \sim (6\times10^{-4}\ \text{s}) B_8^{6/7} R_6^{18/7} (M/M_\odot)^{-5/7} \dot{m}_{17}^{-3/7} \tag{1}$$

where $\dot{m}_{17}$ is the accretion rate in units of $10^{17}\ \text{g s}^{-1}$, B_8 the surface dipole magnetic field in units of 10^8 G, M is the neutron star mass and R_6 is its radius in units of 10^6 cm. In estimating spin-up rates we shall neglect the torque on the magnetized neutron star from currents which flow through it as a result of the termination of its plasma-filled co-rotating magnetosphere at the Alfvén radius by conducting matter of different angular velocity. These may significantly change the spin-up and the dipole moment orientation but not equation (1). The accreted mass needed to achieve this limiting period is then

$$m_a \sim (0.22\,M_\odot) I_{45} (10^3 P)^{-4/3} (M/M_\odot)^{-2/3} \tag{2}$$

where I_{45} is the neutron star moment of inertia in units of $10^{45}\ \text{g cm}^2$, and the required accretion time is

$$T_a \sim 1.4\times(10^8\ \text{yr}) I_{45} (10^3 P)^{-4/3} (M/M_\odot)^{-2/3} \dot{m}_{17}^{-1} \tag{3}$$

The above equations are valid only if B is not so weak that the Alfvén radius shrinks to the stellar surface, that is, $B_8 \gtrsim 0.9\,(M/M_\odot)^{1/4} R_6^{-5/4} \dot{m}_{17}^{1/2}$; otherwise

$$P \sim 2.7\times10^{-4} \left(\frac{M}{M_\odot}\right)^{-1/2} \left(\frac{m_a}{M_\odot}\right)^{-1} R_6^{1/2} I_{45} \tag{4}$$

Immediately after accretion ceases the spun-up neutron star will have a spin-down rate $\dot{P}$ and a lifetime T_s of a freely rotating pulsar:

$$\frac{P^2}{T_s} \equiv P\dot{P} \sim \frac{8\pi^2 R^6 B^2}{3Ic^3} \tag{5}$$

This gives an initial

$$\dot{P} \sim (3.2\times10^{-20}) I_{45}^{-1} (10^3 P)^{4/3} (M/M_\odot)^{5/3} \dot{m}_{17} \tag{6}$$

and initial

$$T_s \sim (10^9\ \text{yr}) I_{45} (10^3 P)^{-1/3} (M/M_\odot)^{-5/3} \dot{m}_{17}^{-1} \tag{7}$$

During its radio pulsar phase the spun-up neutron star thereafter has increasing P and $\dot{P}^{-1}$ related by equation (5).

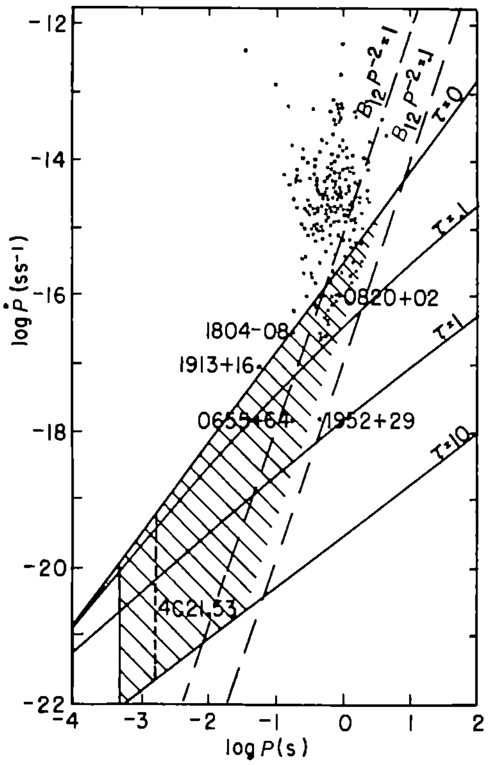

Fig. 1 The $\dot{P}$–P diagram for pulsars, after refs 1 and 17. Dots mark observed values with units as marked. Constant age curves for the new class of accretion spun-up pulsars are shown with $\dot{P}$ values given in units of $I_{45}^{-1}(M/M_{\odot})^{5/3}\dot{m}_{17}$ s s^{-1}. Their pulsar age τ is given in units of (10^9 yr) $I_{45}(M/M_{\odot})^{-5/3}\dot{m}_{17}^{-1}$. After birth at some point on the birth curve ($\tau = 0$) a pulsar is assumed to move on a $P\dot{P}$ = constant line; at age τ it is at the intersection of that line and the curve labelled τ. On hitting the appropriate $B_{12}P^{-2} = \eta$ line ($\dot{P}$ is in units of $R_6^6 I_{45}^{-1}$ s s^{-1} on these lines) it will die out as a pulsar. Thus, all pulsars of the new class should lie in a region similar to the shaded region of the diagram, bounded by the $\tau = 0$ line, the BP^{-2} line, the $\tau \sim 10$ (age of the Universe) line and the line of rotational break-up of neutron stars. These pulsars are confined to that region even when the pre-birth spin-up did not reach the $\tau = 0$ curve (that is, accretion stopped at P longer than equation (1)). It seems that many of the known neutron star binary X-ray pulsars would not become radio pulsars if accretion were to be interrupted now; and some will never become radio pulsars even with continuing spin-up if they are now rotating close to their equilibrium period of equation (1). The possible theoretical ($\dot{P}$, P) points for 4C21.53 lie on the dotted line.

Typical observed accretion rates onto neutron stars in binaries are $\dot{m}_{17} \sim 1$. Almost all radio pulsars[16,17] have $\dot{P}$ larger than initial values from equation (6) followed by spin down (unless $\dot{m}_{17}$ exceeds the Eddington limit by a typical three orders of magnitude). The new class of accretion spun-up pulsars would thus lie in a distinct region of the $P\dot{P}$ plane, bound by the initial conditions of equation (6) and corresponding roughly to observed $\dot{P} < 10^{-17}$ s s^{-1} (Fig. 1). We consider it very significant that this region contains all known binary pulsars as pointed out by Backus *et al.*[1] (Table 1), because binary radio pulsars with collapsed companions are the most promising candidates for old, low B neutron stars which have been spun up by accretion disks[18]. In Table 1 calculated initial $\dot{P}$ for $\dot{m}_{17} = 1$ are compared with observed $\dot{P}$ for these stars. Another potential candidate is the recently discovered radio pulsar 4C21.53 (ref. 19) for which a measured $\dot{P}$ is not yet available and for which there is no direct evidence supporting a present or past binary nature. We believe a history of past spin up by an accretion disk of a low B neutron star may be especially attractive because of the difficulty in understanding this star as a canonical young rapidly spinning pulsar. There appear to be problems in understanding an observation of a millisecond pulsar unless the neutron star had been relatively cold while it was being spun up and has also had a particularly low B ever since. Arguments for low B include the following: (1) A canonical B would give such a rapid spin down that the mere observation of such a pulsar would imply both an extraordinary birth rate and a very large pulsar population with periods between 10^{-3} and 10^{-1} s. We note also that no young supernova remnant is visible. (2) Such rapid spin down ($T_s \sim 1$–10^2 yr) would give internal heating from various mechanisms (crustal flow, superfluid vortex unpinning) that such a neutron star at Crab pulsar distances should have been readily observable by the Einstein Observatory. Observations, however, limit its surface temperature to $<1.5 \times 10^6$ K (D. Helfand and R. H. Becker, personal communication). (3) It would be difficult to account for the absence of observed energetic high energy emission. A spinning neutron star may be expected to have a total current flow and a maximum achievable potential drop along open field lines proportional to BP^{-2}. For the spun-up neutron star

$$\frac{B_{12}}{P^2} = (1.8\times10^2)(10^3 P)^{-5/6} R_6^{-3} (M/M_{\odot})^{5/6} \dot{m}_{17}^{1/2} \quad (8)$$

For $P \sim 10^{-3}$ s and Eddington limit accretion $\dot{m}_{17} \sim 10$, $B_{12}P^{-2} \sim 600$, essentially the same as that of the Vela pulsar and less if the spin-up accretion rate was less than Eddington. There is then no compelling reason to believe that the high energy emission supported by such currents should exceed those from Vela. A millisecond spun-up plusar which resembled Vela but was further away than the Crab pulsar would then certainly be presently undetectable in pulsed optical, X-ray and also in pulsed γ-ray emission below 30 MeV. In higher energy γ rays it may be observable because the period is determined. If $B_{12} \sim 1$, equation (8) would imply a value of $B_{12}P^{-2}$ almost 10^6 that of Vela. (4) It seems difficult for pulsar models which put the source of radiation within the magnetosphere to give GHz radiation when the velocity of light cylinder is near the stellar surface unless the surface B is small. Such models generally utilize e$^{\pm}$ pair production and/or relativistic ion flows. In either case a necessary condition is $B_{12}P^{-2} \gg n$, with n of order unity for e$^{\pm}$ pair production and 10^{-1}–10^{-2} for pure ion flow models. In either case we see from equation (8) that the inequality is easily satisfied for $P \sim 10^{-3}$ s. However, in most models, relevant plasma frequencies are sufficiently high throughout the magnetosphere that expected coherent radio emission is generally at frequencies much above 1 GHz.

If B is indeed to be anomalously low there is an additional reason that a cold, accretion, spin-up scenario is preferred to

Table 1 The binary pulsars and the superfast pulsar as accretion spun-up pulsars with $\dot{m}_{17} = 1$, $M = 1M_{\odot}$ and $I_{45} = 1$

Pulsar	P (ms)	$\dot{P}_{\text{theory}}$ (s s^{-1})	$\dot{P}_{\text{observed}}$ (s s^{-1})	B(G)	T_s (yr)	T_a (yr)
PSR 1913+16	59	7.3×10^{-18}	8.6×10^{-18}	2.1×10^{10}	2.6×10^{9}	6.0×10^{5}
PSR 0820+02	865	2.6×10^{-16}	1×10^{-16}	4.8×10^{11}	1.0×10^{8}	1.7×10^{4}
PSR 0655+64	196	3.6×10^{-17}	$<5\times10^{-18}$	8.6×10^{10}	1.7×10^{8}	1.2×10^{5}
4C21.53	1.5	5.5×10^{-20}	?	2.9×10^{8}	8.9×10^{8}	8×10^{7}

$\dot{P}_{\text{theory}}$ is calculated from equation (6) on assuming that the presently observed P is still the initial one. Because, in fact, both P and $\dot{P}^{-1}$ are expected to increase roughly by equation (5), one expects $\dot{P}_{\text{theory}} \gg \dot{P}_{\text{observed}}$.

a hot, supernova, one. Even if a high spin, low magnetic field pulsar could be formed in a supernova (and thus retain a high spin for times much longer than its cooling time), the large heat flux from that hot neutron star may still generate sufficiently large crustal magnetic fields by magnetothermal effects[10]. The neutron star would then spin down before the B field dissipated and thus have a period far longer than a millisecond. By contrast, in the presence of ohmic dissipation, the much smaller stellar heating during the accretion phase need not generate large magnetic fields[10].

We note that the predicted initial $\dot{P}$ of 4C21.53 as a superfast spun-up pulsar is $<5.5\times10^{-20}\,\mathrm{s\,s^{-1}}$ $(I_{45}^{-1}(M/M_{\odot})^{5/3}\dot{m}_{17})$. A larger $\dot{P}$ could indicate the presence of non-electromagnetic, for example, gravitational radiation torques.

The expected lifetime as X-ray sources of the low mass galactic bulge close binaries has been estimated to be of order 10^9 yr. If a large fraction do indeed end up as the single spun-up neutron stars of scenario (1) (many, perhaps, still in the dilute cloud formed by that part of the primary which was not accreted), the relative number of radio pulsars to neutron star X-ray sources would be of order $T_s/10^9\,\mathrm{yr}\sim1$. As there are of the order of 25 such neutron star X-ray sources[6] we might then expect a similar number of fast accretion-spun-up radio pulsars in the Galaxy. Almost all will be well beyond the $\sim6\times10^3$ light yr limit for pulsar detectability but to observe one or two does not seem implausible. Certainly it is among the galactic bulge X-ray sources that millisecond neutron star periods might be common.

Persistent X-ray emission from a γ-ray burst source

A quiescent X-ray source detected with the Einstein X-ray Observatory in a location consistent with that of an intense γ-ray burst[1–3] is shown here to be also consistent with the location of the 1928 optical transient[4], the likely optical counterpart of the γ-ray burst source GBS0117−29. The probable maximum X-ray luminosity is only $\sim10^{31}\,\mathrm{erg\,s^{-1}}$ and supports the hypothesis that either γ bursts are produced by accretion instabilities[5,6] or, if due to published models for a thermonuclear flash[7], they recur with intervals $\geqslant$50 yr. Such long recurrence times may be inconsistent with limits inferred from both the γ burst observations[8] and optical data[4].

The interplanetary burst network timing of γ bursts has yielded several relatively precise error boxes for source locations. One of these, the $\sim5\,\mathrm{arc\,min^2}$ location[1] of the γ burst detected on 19 November 1978 (GBS0117−29) led to the discovery of its probable optical counterpart from a brief optical transient found on a 1928 Harvard patrol plate[4]. The γ burst location was sufficiently precise that a search for an accompanying X-ray[1–3] and radio[9] counterpart could be carried out. A $\sim$9,000 s X-ray guest investigation observation[2,3] has been conducted with the IPC detector on the Einstein X-ray Observatory[10] on 1–2 July 1980. Preliminary analysis of these data yielded a 3.5σ source detection with a relatively large location uncertainty in which the optical transient was later found. These X-ray data have been recently reprocessed using an improved analysis system with the result that both the source detection and its positional coincidence with the transient optical counterpart are established. Further studies of this X-ray source, as well as upper limits from Einstein observations of several other γ burst positions, are reported elsewhere[11].

The new source location is plotted in Fig. 1, together with the position of the optical counterpart[4] and the original γ burst error box[1]. The X-ray source error box has a 90% confidence radius of 45 arc s and is centred 42 arc s north-west of the optical counterpart. The X-ray flux detected in the 'hard' 0.5–3.0 keV band is $1.0\times10^{-13}\,\mathrm{erg\,cm^{-2}\,s^{-1}}$. From the recent determination of log N–log S for high latitude X-ray sources[12], the probability that an X-ray source with flux $\sim1\times10^{-13}\,\mathrm{erg\,cm^{-2}\,s^{-1}}$ should be found within 1 arc min of the optical counterpart is only 1.7×10^{-3}. The consistency of the position of the persistent X-ray source with that of the optical transient link its identity to the larger source location region for the γ-ray burst. The 19 November 1978 burst was among the most intense ever recorded, which may account for the apparent absence[11] of other persistent X-ray counterparts (omitting the anomalous case of the 5 March 1979 burst apparently from the supernova remnant N49).

As the steady X-ray source was not detected in the 'soft' 0.15–0.5 keV band and no significant low energy absorption is expected at the −83° galactic latitude position it seems that the source is not a coronal emission source (for example, stellar X-ray emission from an M dwarf), but is instead an accretion source with a characteristically hard ($kT\geqslant2$ keV) spectrum. Too few counts were detected to allow useful spectral fits, hardness ratios, or low energy cutoffs to be determined from the data. A temporal analysis was carried out, however, and shows that the X-ray emission is consistent with a constant flux throughout the entire 9,000 s observation.

The probable optical counterpart of the 1928 optical transient and γ buster was detected[4] with quiescent magnitude $\geqslant$23 on the B and V 4-m plates of M. Liller. However, deeper searches carried out a month later with a 1.3-m telescope and CCD camera[13] gave upper limits of magnitude $\sim$25. Subsequent more sensitive CCD observations[14] have detected the quiescent and possibly variable emission from the source at magnitude $\sim$25. Thus the optical flux appears to be variable by a factor of at least 10 on time scales no more than $\sim$1 month. Presumably the quiescent X-ray flux is also variable although follow up X-ray observations are needed. The ratio of X-ray to optical luminosity is therefore poorly constrained but is probably in the range $L_x/L_{\mathrm{opt}}\simeq6$–60. This is similar to that found for low-mass X-ray binaries where the optical light arises from an accretion disk rather than the non-degenerate stellar com-

0028–0836/82/510730—02$01 00

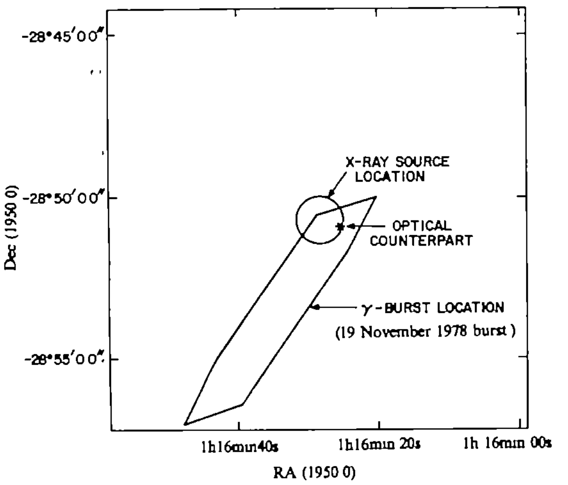

Fig. 1 Location (90% confidence error circle with 45 arc s radius centred at RA(1950) = 01 h 16 min 28.58 s, dec(1950) = −28°50′42″) of the quiescent X-ray source which is the probable counterpart for the γ-ray burster GBS0117−29. The interplanetary network position for the 19 November 1978 γ burst[1] and the location of the 1928 optical transient[4], the probable optical counterpart, are also shown.

panion. The L_x/L_{opt} value is probably not consistent with the value expected for an isolated neutron star accreting from an interstellar cloud but is intermediate between the typical values for compact binaries containing accreting degenerate dwarfs (with $L_x/L_{opt} \sim 1$) or accreting neutron stars (with $L_x/L_{opt} \sim 10^3$). Since the super-Eddington luminosities inferred for some γ bursts as well as the possible detection of both redshifted positron annihilation line radiation as well as possible cyclotron features all point strongly to a magnetized neutron star origin for γ bursts[15–17], we shall explore the consequences of this interpretation.

Our estimate for L_x/L_{opt} suggests that the system is underluminous (relative to compact binaries containing neutron stars) in X rays by perhaps a factor of 10. This could be due to the non-simultaneity of the X-ray and optical observations and/or to a highly variable accretion rate. Alternatively, it may indicate a relatively low accretion rate and a variable 'additional' optical contribution from cyclotron radiation in a $\sim 10^8$ G field at an effective Alfvén surface, where matter may accumulate before a burst. If the bursts are due to Rayleigh–Taylor like instabilities of $\sim 10^{19}$ g of matter (required for an $\sim 10^{39}$ erg total energy burst) accumulated in a magnetospheric shell, its radius would be $R \sim 2 \times 10^7$ for an assumed surface field $B \sim 1 \times 10^{12}$ G. The (assumed dipole) magnetic field in the shell would then in fact be $\sim 10^8$ G. Note that black-body radiation from the shell would not dominate the optical cyclotron radiation if the thermal temperature of the magnetospheric shell is $T \leq 4 \times 10^4 K$. Note also that such a 'shell' must, in fact, be a disk-geometry (a thick ring in the accretion disk?) since its large column density ($\sim 10^{28}$ cm^{-2}) would be opaque to quiescent X rays from the central neutron star.

The observed X-ray flux would require (for an assumed maximum distance of 1 kpc and $L_x \simeq 10^{31}$ erg s^{-1}) an accretion rate of $\simeq 1 \times 10^{-14}[d(1\text{ kpc})]^2 M_\odot$ yr^{-1}. This value is probably too low to be consistent with published nuclear flash models for γ bursts[7,16] unless the distance is substantially greater than ~1 kpc or the burst recurrence time is ≫50 yr, the accretion rate is highly variable, or further theoretical work on flash models shows that flashes yielding $\sim 10^{39}$ erg can be produced with a total accumulated mass of only $\sim 10^{20}$ g (as required for a ~5–10 yr recurrence time at the derived accretion rate). Such a large distance would make GBS0117−29 a halo object, whereas the isotropy and size distribution for γ bursts in general suggests[18] that they are an extended disk population in the Galaxy. Such a long recurrence time appears to be inconsistent with the detection of the optical burst[4]. A highly variable (factor of ≫50) accretion rate, while somewhat *ad hoc*, cannot be ruled out, and it might, in fact, be suggested by the variable optical flux. Once again, repeated X-ray observations are needed. However, if the average accretion rate and X-ray luminosity vary only by factors of ~3, as do most neutron star X-ray binaries (we may exclude X-ray transients, as their quiescent L_x/L_{opt} values are probably much lower than observed for this quiescent γ burster), we conclude that the accretion instability models[5,6] for γ bursts may be preferred.

If the quiescent X-ray emission from GBS0117−29 is typical, the summed X-ray flux from all such objects could be significant. For a currently extrapolated total of ~150 bursts yr^{-1} (ref. 19), and an assumed typical source distance of 300 pc and ~1 yr burst recurrence time, the volume density of γ bursters is $\sim 1.5 \times 10^{-6}$ pc^{-3}. This is within an order of magnitude of the value derived by Hertz and Grindlay[20] for low-luminosity ($\sim 10^{31}$ erg s^{-1}) accretion X-ray sources in the Galaxy as measured by the galactic plane survey carried out with the Einstein Observatory. Most of these low luminosity ($\sim 10^{31}$ erg s^{-1}) X-ray sources are probably cataclysmic variables but it is possible that some are the quiescent counterparts of γ burst sources. Given the similarities in space density, it is also possible that the γ bursters are a large fraction of the neutron star products of cataclysmic variable evolution wherein continued accretion onto a degenerate dwarf eventually violates the Chandrasekhar limit and collapse to a neutron star ensues. Such systems might also be expected to have evolved (by mass transfer) such low mass non-degenerate stellar companions that their absolute magnitudes would be consistent with the stringent limits ($M \geq 15$, assuming $d \leq 1$ kpc) recently derived[13,14] for the GBS0117−29 source.

The tide in the seas of Titan

Carl Sagan & Stanley F. Dermott

Laboratory for Planetary Studies, Cornell University, Ithaca,
New York 14853, USA

The surface temperature of Titan[1] is about 95 K, between the melting point (90.6 K) and the boiling point (118 K) of methane at the total surface pressure of 1.6 bar. Voyager 1 IR observations[1,2] suggest a methane abundance in the lower atmosphere >0.19 of saturation. Comparison with the mean H_2O abundance in the Earth's atmosphere suggests[1] a CH_4 saturation level ≅0.5. Thus the volume mixing ratio of methane is probably about 6% and methane begins to condense out some 40 km above the surface. It is therefore a natural speculation that

methane exists in the liquid state on the surface of Titan. The atmospheric CH_4 corresponds to a liquid layer ~10 m deep. But it is unlikely that the buffer for atmospheric methane would have a capacity equal only to that of the atmosphere itself. On Earth, the quantity of water in the oceans is on average several times 10^4 the quantity of water vapour in the atmosphere. Thus, if Titan has oceans of liquid CH_4, they are probably >100 m deep. We argue here that, if this ocean exists, the present high eccentricity of Titan requires its depth to be >400 m, and that such an ocean can be detected by radar techniques.

The relief observed on other saturnian moons, such as Tethys and on jovian moons of comparable size, such as Ganymede, is ~1 km in scale[3]; we would anticipate comparable relief on the surface of Titan. Initially, therefore, we expect both land and sea on Titan. The interaction of UV light and charged particles with the titanian upper atmosphere produces a class of dark organic solids called tholins[4-7], which are expected over geological time to coat the land and accumulate as submarine deposits to a depth also in excess of 100 m (ref. 8).

Saturn will raise a significant tide in the seas of Titan, but because the satellite is probably in synchronous rotation with a period of 15.95 days the tide will be near-stationary and centred close to the Saturnward radius vector. If the solid body of Titan has not relaxed to hydrostatic equilibrium, then the maximum height of the solid body tide will be[9,10]

$$s = \frac{(5/2)(M_S/M_T)(R^4/a^3)}{1+\tilde{\mu}[1-(3\sigma/5\rho)]/[1-(\sigma/\rho)]} \qquad (1)$$

and the difference between the maximum heights of the oceanic and body tides will be

$$h = \frac{(M_S/M_T)(R^4/a^3)}{[1-(3\sigma/5\rho)]+[1-(\sigma/\rho)]/\tilde{\mu}} \qquad (2)$$

where M_S and M_T are the masses of Saturn and Titan, respectively; R is the surface radius of Titan; a is the semi-major axis of Titan's orbit; $\sigma = 0.45$ g cm^{-3} is the density of the putative titanian ocean; $\rho = 1.88 \pm 0.01$ g cm^{-3} is the mean density of Titan[3]; and $\tilde{\mu} = 19\mu/2\rho g R$, where μ is the rigidity of the solid body of Titan and g is the surface acceleration due to gravity. The greater the rigidity, the greater will be the amplitude h of the apparent oceanic tide.

The mean density of Titan is intermediate between the uncompressed densities of ice and rock; the solid body of the satellite is likely to consist of an icy mantle and a rocky core. The rigidity of water ice at temperatures near 100 K is 4×10^{10} dyn cm^{-2} (ref. 11). For methane and ammonia ices and their clathrates, μ should not be significantly less. The rigidity of rock in the interior of Titan will be larger. The central pressure is bounded by the following inequality[12], which is independent of the equation of state: $P_0 \leqslant P_c \leqslant (\rho_c/\rho)^{4/3}P_0$ where $P_0 = 3GM_T^2/8\pi R^4$. Allowing the central density, ρ_c, to range as high as 5 g cm^{-3}, we find $33 \leqslant P_c \leqslant 118$ kbar, a pressure range corresponding to that of the upper mantle of the Earth down to ≃350 km depth, a region[13] in which μ is $\sim 0.7\times 10^{12}$ dyn cm^{-2} and varies slowly with depth. Thus, we obtain a lower bound on μ and h by adopting the rigidity of water ice. Then, $\tilde{\mu} \gtrsim 6$, and

$$h \gtrsim 100 \text{ m} \qquad (3)$$

for the amplitude of the apparent, near-stationary, oceanic tide on Titan. Tides generated by the other saturnian moons have sub-millimetre amplitudes.

The possible existence of an ocean on Titan requires us to reconsider the effects of tidal dissipation. Previous studies[14] treat the effects of dissipation in the solid body of the satellite; but, as on Earth[13], solid body dissipation may be negligible compared with oceanic dissipation. There is no direct evidence that Titan is in synchronous rotation, but the time scale to achieve synchronicity is estimated[15] at 10^7–10^8 yr. The orbital eccentricity of Titan, $e = 0.0289$, is comparatively high. Tidal distortion decreases as the cube of the distance; thus, the amplitude of the tide raised by Saturn on the satellite will vary by a factor of $3e$, or 9% over its 15.95-day period. Titan rotates such that one face is directed towards the empty focus of its orbit, whereas the tide raised on it by Saturn is directed towards the planet. Consequently, the tide oscillates across the face of the satellite. The energy loss associated with these oscillations could, over the age of the Solar System, result in significant damping of the orbital eccentricity. As there appear to be no mechanisms available to increase e, the observed eccentricity can be used to establish limits on the surface topography and oceanic depths of Titan.

If the solid body of Titan has relaxed to near-hydrostatic equilibrium, then the maximum height of the mean solid body tide is given by equation (1) with $\tilde{\mu} = 0$. We have $s \leqslant 250$ m where the deviation from the upper limit is determined by the degree to which Titan is centrally condensed: the tide height is 250 m only if the density of the satellite is uniform[16]. It would also follow for hydrostatic equilibrium that $h = 0$, and if the orbit of Titan were circular then the depth of a shallow ocean would be everywhere the same and independent of the phase of the orbital period. However, as we have already noted, the orbit of Titan is far from circular. Since all deformations are small and can be added linearly, and since for short period oscillations the rigidity of the solid body cannot be ignored, then, regardless of the degree of relaxation of the solid body, the amplitude of the apparent oceanic tide will vary by an amount $3eh$ ($\gtrsim 9$ m) over a 15.95-day period, where h is given by equation (3).

Because the effect on e of the tide raised on Saturn by Titan is negligible[14], the time constant τ for the decay of the orbital eccentricity is given by[14,17]

$$\tau = \frac{2}{21}\frac{M_T}{M_S}\left(\frac{a}{R}\right)^5\frac{Q}{nk_2} \qquad (4)$$

where n, k_2 and Q are the mean motion, the Love number and the specific dissipation function of Titan respectively. Thus, $\tau = 4\times10^6\, Q/k_2$ yr and unless $Q/k_2 \gtrsim 1{,}200$, τ is less than the age of the Solar System and the present comparatively high value of e is difficult to understand.

The Love number is determined by the internal density and rigidity distributions and can be written[16] as $k_2 = (5/2)[H-(2/5)]$, where $H \leqslant 1$ and is unity only for a homogeneous satellite in hydrostatic equilibrium. Since $\tilde{\mu} \gtrsim 6$ the distortion of Titan's solid body is small and H can be estimated[16] from a point-core model as $H = (2/5)[1-(3\sigma/5\rho)]^{-1}$. Substituting, we find $k_2 = 0.17$. Hence, for $\tau > 4{,}600$ Myr, we must have

$$Q > 200 \qquad (5)$$

If the putative titanian ocean is global in extent, then the above lower bound on Q effectively rules out the existence of large land masses, which, as on Earth, would act as barriers to the tidal flow and would generate low values of Q (~10). If the ocean cover is nearly complete, then Q may be large (>200), but only if the mean depth D of the ocean is also large so that oceanic boundary layer turbulence is weak. Following Goldreich and Soter[18] we estimate that the rate of energy loss due to boundary layer turbulence is $\dot{E} = f\sigma\langle v^3\rangle$ erg cm^{-2}, where $f \approxeq 0.002$ is the coefficient of skin friction and v is the local velocity of the tidal current. The time-dependent part of the tide-raising potential of Saturn at some point (R, θ, ϕ) on Titan is

$$V = -\frac{GM}{a}\left(\frac{R}{a}\right)^2 3e$$
$$\times[\tfrac{1}{2}(3\sin^2\theta\cos^2\phi - 1)\cos nt + \sin^2\theta\sin 2\phi\sin nt] \qquad (6)$$

The first term in equation (6) excites the radial tide due to the variation in Saturn's distance and the second term is due to the optical libration of Titan. We estimate that the average tidal flow due to the radial tide alone is given by

$$\langle v^3\rangle^{1/3} = (2/105\pi^2)^{1/3}(3eh/D)nR \qquad (7)$$

where v^3 has been averaged over the surface of the satellite and over one tidal cycle. This estimate neglects the effects of coriolis forces, which act to increase the tidal flow rates; thus, our value of $\langle \dot{E} \rangle$ is an underestimate.

We set $\langle \dot{E} \rangle = ce^3$. Then, since the total orbital angular momentum of the system is conserved (the spin angular momentum of Titan is negligible), one can show that

$$\dot{e} = -ce^2/E \qquad (8)$$

where E is the total orbital energy. As the initial eccentricity of Titan's orbit must be <1, integration of equation (8) yields

$$|c| < |E|/et \qquad (9)$$

where t is the age of the system. If we now write $\langle \dot{E} \rangle = x\langle \dot{E}_r \rangle$, where $\langle \dot{E}_r \rangle$ is the energy loss due to the radial tide alone, then on substitution we find that equation (9) is satisfied only if

$$D > 300x^{1/3}\text{m} \qquad (10)$$

We estimate that, for the combined radial and libration tides, $x > 2$ and that the effects of coriolis forces will act to increase this limit further. Hence, we conclude, conservatively, that

$$D > 400\text{ m} \qquad (11)$$

Equations (1) and (2) for the tide heights assume that the kinetic energy of the tidal flow is negligible compared with the potential energy: the tides are assumed to be in static equilibrium. This is the case for the oceanic tide only if $D \gg (1/10)(nR)^2/g = 10$ m, a condition[19] which our previous arguments suggest is satisfied on Titan. If D were $\approxeq 10$ m, then the kinetic and potential energies would be comparable and we would expect enhanced dissipation and a reduced Q due to resonance in tidal basins. This is a further argument for a deep ocean. The velocity of the tidal current will be $v \simeq (h/4D)$ m s^{-1}, providing a possible source of erosion especially in shallows and on the equivalent of continental margins. It is therefore conceivable that the eccentricity-driven departure from a pure stationary tide has, over geological time, eroded away most of the land masses on Titan, and is thereby responsible for the large value of Q [equation (5)].

Accordingly, there seem to be two internally consistent possibilities: (1) a near-global methane ocean >400 m deep that has inundated or eroded away most of the land on Titan, and (2) almost no methane ocean at all. In the latter case, the position of the surface of Titan near the liquidus in the CH_4 phase diagram will have to be considered a distracting coincidence, and the observed atmospheric methane must maintain itself against photolysis by some mechanism other than the equilibrium vapour pressure resupply from a methane ocean[8]. Fortunately, the choice between these alternatives can be made by remote observations.

The dielectric constant, ε, at microwave frequencies of liquid methane at the surface temperature of Titan is[20] about 1.7. As the square of the imaginary part of the complex refractive index, $k^2 \ll (\sqrt{\varepsilon} - 1)^2$, the normal-incidence Fresnel equation yields a microwave reflectivity for a smooth methane ocean of about 0.017. For many organic solids $\varepsilon \approxeq 2.6$ at visible wavelengths, increasing to 4–6 at microwave frequencies. X- and S-band values of ε for tholins have not yet been measured, but are likely to be in this range. The corresponding normal-incidence Fresnel reflectivities, with the same condition on k, range from 0.05 to 0.18. Thus we expect a contrast between the microwave reflectivity of methane oceans and tholin-covered land ranging between a factor of several and a factor of 10. If the land is not entirely inundated and the solid body has not relaxed to near-hydrostatic equilibrium, then we might expect a systematically higher radar reflectivity near the 0° and 180° meridians. If the solid body has relaxed then we might expect small variations in the disk-integrated reflectivity at a constant central meridian longitude with a period of 15.95 days.

Preliminary attempts to observe Titan near elongation with the 305-m Arecibo telescope during the 1979 opposition set only an upper limit of unity to the radar reflectivity (D. Campbell and S. Ostro, personal communication). Considerably higher precision can be expected during the next Arecibo apparition of Titan in the mid-1990s, which can also check whether Titan is in fact in synchronous rotation. These considerations make still more interesting recent proposals to examine Titan, from orbit or from a probe-carrying flyby bus, with a spaceborne radar reflectometer.

Design of a 13% efficient n-$GaAs_{1-x}P_x$ semiconductor–liquid junction solar cell

Chris M. Gronet & Nathan S. Lewis

Department of Chemistry, Stanford University, Stanford,
California 94305, USA

We report here the design of the most efficient non-aqueous semiconductor–liquid junction solar cell studied to date. Our approach involves the use of ternary semiconductor electrodes made from solid solutions of a large band gap material, GaP, and a small band gap material, GaAs. We demonstrate here that photoanodes consisting of such materials are capable of simultaneously yielding high open circuit voltages and favourable wavelength response to the solar spectrum. A few n-type semiconductor–liquid junction solar cells in aqueous solutions have been reported to yield high (>10%) solar-to-electrical conversion efficiencies[1–3]. However, for most materials, rapid photoanodic corrosion dominates the interfacial photochemistry[4–8]. Non-aqueous solvent systems can suppress electrode decay due to corrosion[4,7,8]; but modest (<6%) conversion efficiencies have been observed for all photoanodes studied in solar irradiation conditions[9–13]. The photoanodes used here yield over 13% solar-to-electrical conversion efficiencies, or more than double the efficiency of any other non-aqueous semiconductor–liquid junction solar cell previously reported.

We have studied a set of compositions of $GaAs_{1-x}P_x$, $0 < x \leqslant 1$, obtained as epilayers deposited on n^+-GaAs or n^+-GaP substrates by vapour phase epitaxy techniques. The epilayer is thick enough (0.1 mm) to prevent any photoactivity in the substrate. This has been verified by the lack of photocurrent on excitation of $GaAs_{1-x}P_x$ ($x \geqslant 0.3$) samples on n^+-GaAs substrate with light $\lambda \geqslant 750$ nm.

Composition of the epitaxial layers used was verified by electron microprobe analysis and found to be: $GaAs_{0.85}P_{0.15}$, $GaAs_{0.72}P_{0.28}$, $GaAs_{0.61}P_{0.39}$, $GaAs_{0.38}P_{0.62}$, $GaAs_{0.31}P_{0.69}$, and

0028–0836/82/510733—03$01 00

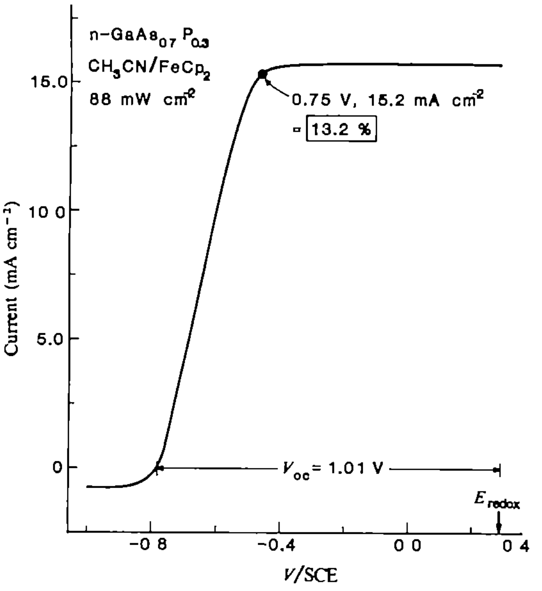

Fig. 1 Current–voltage curve at 50 mV s^{-1} (88 mW cm^{-2}) of a sample of n-GaAs$_{0.72}$P$_{0.28}$ in 0.1 M Fc/0.5 mM Fc$^+$/ACN. The electrolyte is 1.0 M (Et$_4$N) BF$_4$, and the solution is stirred magnetically. The solution potential is +0.22 V/SCE, and photocurrent negative of this potential represents net conversion of light into electricity.

GaAs$_{0.05}$P$_{0.95}$. Increasing the P content of the samples increases the band gap, E_g, in a monotonic, but not linear fashion, from 1.44 eV ($x = 0$) to 2.25 eV ($x = 1$) (ref. 14). A direct-to-indirect gap transition occurs at composition $x = 0.44$, with n-GaP having an indirect gap of 2.25 eV and a direct gap of 2.75 eV. Samples (0.1 cm^2) were mounted as photoelectrodes by conventional techniques. Ohmic contacts were formed by evaporation of In at 1×10^{-6} torr and annealing under N_2 at 400 °C for 15 minutes. Potentials were recorded versus either a standard calomel reference electrode or a Pt wire placed ~1 cm from the working electrode. We have made no effort to minimize or instrumentally correct for the uncompensated ohmic resistance (~50 Ω) in this cell design; thus the efficiencies reported here are conservative by 10–20%. Light sources were either the Sun, a calibrated W-halogen ELH-type lamp with a ground glass diffuser, or a 5 mW He/Ne laser. Light intensities were measured with a Solarex secondary standard silicon cell and verified to within 10% by an Eppley thermopile. For samples with $E_9 < 2.0$ eV, we consistently find differences in efficiency measurements between our calibrated ELH lamp and actual sunlight of <10%. The samples were etched with 1 : 1 HF/H_2O_2 for 15 s, rinsed with H_2O, and air dried before use.

W-halogen irradiation (88 mW cm^{-2}) of a sample of n-GaAs$_{0.72}$P$_{0.28}$ (not deliberately doped; $N_D = 3.3\times10^{15}$) in the solution 0.1 M ferrocene (Fc), 0.5 mM Fc$^+$ in dry acetonitrile (ACN) solvent (electrolyte 1.0 M $(C_2H_5)_4N^+BF_4^-$) typically yields the current–voltage profile represented in Fig. 1. We observe an open-circuit voltage, (V_{oc}), of 1.01 V, a short-circuit current of 15.7 mA cm^{-2}, and a fill factor of 0.73, leading to an optical-to-electrical conversion efficiency of 13.2% (15.2 mA cm^{-2} and 0.76 V at the point of maximum power). In natural sunlight (64 mW cm^{-2}), we observe similar behaviour, and conversion efficiencies of 12.5–13.0% are typical.

For comparison with other literature data, we have also recorded the current–voltage characteristics at 632.8 nm with a He–Ne laser. Values are consistent with the W lamp data, and at intensities of 20 mW cm^{-2} we observe over 22% efficiency for conversion of monochromatic 632.8 nm light to electricity.

The extremes of our series, n-GaAs and n-GaP, have been previously studied in ACN electrolytes. n-GaAs, with E_g = 1.44 eV, is ideally suited for terrestrial solar applications; however, in similar non-aqueous cells, it is reported to yield modest operating voltages (0.25 V) (ref. 15), low quantum efficiencies (0.3) (ref. 16), and fill factors which decline at irradiation levels above 0.01 suns[15], leading to solar conversion efficiencies of 2.4% (ref. 15). n-GaP is reported to yield output voltages of up to 0.8–1.0 V (ref. 17). However, its E_g (indirect) of 2.25 eV leads to low short-circuit currents and poor solar efficiency. The goal of our studies with GaAs$_{1-x}$P$_x$ was to maintain the high output voltage characteristics of n-GaP with the favourable solar wavelength response of GaAs.

We observe much larger values of V_{oc} with n-GaAs$_{0.72}$P$_{0.28}$ than reported for n-GaAs. A comparison of our GaAs$_{1-x}$P$_x$ data with the performance of GaAs (refs 15, 16) suggests that substitution of P for As in the GaAs lattice eliminates most of the sources of inefficiency in ACN solvent. Consistently, we observe high values of the fill factor, >0.70 for all samples with $x \geq 0.25$, which are fairly independent of light intensity even at irradiance levels near 1 Sun.

A plot of V_{oc} at 88 mW cm^{-2} in Fc/Fc$^+$/ACN solution as a function of x (Fig. 2) shows that even for low levels of P, ($x = 0.3$), V_{oc} has increased to 1.01 V. Further increases in x lead to smaller changes in V_{oc}. As expected, the short-circuit currents measured with our W-halogen irradiation source decrease with increasing value of E_g (ref. 18). Thus, there is a maximum P content for optimum cell efficiencies, and for the range of samples studied, this occurs with GaAs$_{0.72}$P$_{0.28}$, E_g = 1.77 eV. An E_g of 1.4 eV is optimum for AM1 solar conversion devices[19], and increasing the E_g to 1.77 eV decreases the maximum theoretical AM1 conversion efficiency from 36 to 32% (ref. 19). However, for these GaAs$_{0.72}$P$_{0.28}$ samples, the increased values of both V_{oc} and the voltage at maximum power (V_{pmax}) compared with those reported for n-GaAs in non-aqueous systems results in much higher efficiencies for the larger E_g materials used here (n-GaAs$_{0.72}$P$_{0.28}$: $V_{oc} = 1.01$, $V_{pmax} = 0.76$; n-GaAs: $V_{oc} = 0.62$, $V_{pmax} = 0.25$).

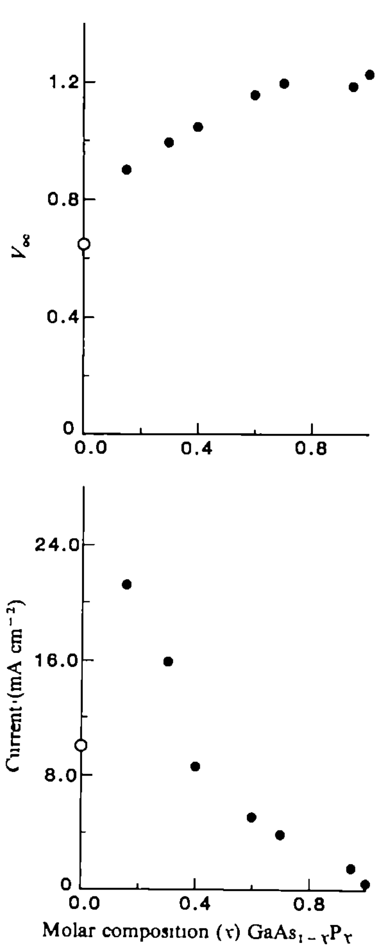

Fig. 2 Plot of open-circuit voltage and short-circuit current against composition for n-GaAs$_{1-x}$P$_x$. All measurements were performed in conditions identical to those in Fig. 1. ○, Previously reported data for n-GaAs, taken from refs 15 and 16.

We have studied changes in V_{oc} for our n-$GaAs_{0.72}P_{0.28}$ as a function of solution potential, $E°$, with a variety of redox reagents. As measured by either cyclic voltammetry or steady-state current–voltage curves, we find that V_{oc} is relatively constant (0.95 ± 0.10 V) for a range of redox couples whose $E°'$ spans more than 1.5 V. For example, we find that the photoanodic peak in a cyclic voltammogram (a measure of V_{oc})[20] for n-$GaAs_{0.72}P_{0.28}$ appears at -0.71 V/SCE for Fc oxidation (E_p at Pt $= +0.30$ V/SCE) and for the leuco form of methyl viologen, MV°, at -1.86 V/SCE (E_p at Pt $= -0.85$ V/SCE). Such behaviour has been observed for several semiconductor–liquid interfaces, and has been attributed to either carrier inversion at the surface[21] or to a high density of surface states[22] which act to pin the surface Fermi level to values independent of the solution $E°$. Such situations, as in non-aqueous n-GaAs systems,[15] limit the maximum V_{oc} attainable and can yield lower than optimum conversion efficiencies. Substitution of P for As in the lattice of n-GaAs leads to stronger bonding in both the bulk and surface regions of the material. Initial increases in x thus produce a highly favourable shift in factors controlling V_{oc}, with only a slight increase in E_g. Further increases in x yield little improvement in V_{oc}, only serve to increase the value of E_g, and thereby lower the overall efficiency.

Deliberately dried ACN solutions (3-Å sieves) yield extremely reproducible (±5%) current–voltage parameters over periods of hours with no visible surface damage or deterioration of cell properties. As reported for n-GaAs in ACN, injection of small amounts of H_2O (for example 75 mM H_2O) leads to rapid photocurrent decay, presumably due to oxide formation[15]. At present, we have observed stable photocurrents (±10%) at 15 mA cm^{-2} with n-$GaAs_{0.72}P_{0.28}$ for passage of over 10^3C cm^{-2} at short circuit with no apparent weight loss of the crystal or visible surface damage. We have ruled out substantial photocorrosion with experiments using thin (5 μm) epilayers of n-$GaAs_{0.72}P_{0.28}$ on n^+-GaAs. Assuming a six electron decomposition process, consumption of the entire epilayer in this 2.5×2.5 mm crystal would require ~1 C of charge. After passage of over 30 C through this particular crystal, we still observe the V_{oc} and wavelength response of the n-$GaAs_{0.72}P_{0.28}$ epilayer with no apparent contribution from the substrate. Photocorrosion processes would thus appear to be minimal. Long-term experiments are in progress, and the ultimate stability of these systems will probably depend on the extent to which water can be excluded from the electrolyte, solvent, and cell environment.

We note that our 13% efficiencies have been obtained on electrode surfaces with no deliberate attempts to optimize fully donor densities, reflectivity losses, and surface treatments. Such procedures have been shown to improve the performance of several aqueous photoelectrochemical systems in conditions similar to those utilized here[23]. We are developing such optimization procedures for our photoelectrodes, as well as studying the effect of ion implantation of P into the surface region of n-GaAs. The high efficiencies of the $GaAs_{1-x}P_x$ system demonstrate that properly designed non-aqueous electrolyte based photoelectrochemical cells can provide efficiencies competitive with aqueous systems. Moreover, control of V_{oc} by varying bulk composition can be an important approach to the design of efficient semiconductor–liquid junction cells, as evidenced by the dramatic improvements in efficiency observed with our photoelectrode materials. At present, the 13% solar conversion efficiency for n-$GaAs_{0.72}P_{0.28}$ system represents the highest value reported for any semiconductor–liquid junction cell in actual solar conditions.

We thank J. Gibbons and G. Cogan of SERA Solar Corporation for helpful discussions and for formation of ohmic contacts to the crystals, and L. Stinson and R. Ferraro of Hewlett–Packard and C. L. R. Lewis of Varian Associates for donating samples.

Nuclear weapons tests at oceanic sites during the 1950s produced a large amount of ^{36}Cl ($t_{1/2} = 3.0 \times 10^5$ yr) through neutron capture of ^{35}Cl in seawater. Part of this anthropogenic ^{36}Cl was injected into the stratosphere from where it was redistributed throughout the Earth. This pulse of ^{36}Cl was first detected in rainfall by Schaeffer *et al.*[1]. The global deposition rates are several orders of magnitude larger than the natural pre-and post-bomb ^{36}Cl production rate that reflects cosmic-ray spallation of atmospheric ^{40}Ar. Because ^{36}Cl is not a fission product, the anthropogenic ^{36}Cl is produced mainly in marine tests carried out on small islands and barges where a large amount of seawater chlorine is present to serve as a target. This target element requirement leads to a temporal dependence different from the other bomb produced isotopes[2–4]. We have determined the temporal dependence of ^{36}Cl fallout by measuring the depth profile of ^{36}Cl in an ice core from Dye 3 Greenland (65° 11′ N, 43° 50′ W) using tandem accelerator mass spectrometry[5]. We show here that the results agree well with a calculation of the ^{36}Cl produced and injected into the stratosphere by the tests.

The samples were prepared from a 100-m ice core drilled at Dye 3 in 1980 as a side project of the US–Danish–Swiss Greenland Ice Sheet Program (GISP). Based on space charge measurements[6], the core was cut at the site into pieces containing the precipitation of approximately 1 yr. The $\delta^{18}O$ profile determined later (W. Dansgaard, personal communication) showed that the actual intervals ranged from 0.5 to 1.5 yr (Table 1). The sample weights ranged from 0.9 to 2.2 kg. Before adding Cl carrier (1.52 mg Cl) and Be as carrier (for ^{10}Be measurements that will be reported elsewhere) to the melted ice, an aliquot was taken for chloride analysis. The natural chloride content, measured by ion chromatography for several of the samples, was found to be about 50 μg per kg-ice and thus contributed only ~3% to the chloride content of the prepared sample. The chloride was separated by precipitation of AgCl and purified as described elsewhere[7].

The ^{36}Cl concentrations were measured using the University of Rochester's MP tandem van de Graaf accelerator facility. A major improvement to the system since our previous ^{36}Cl

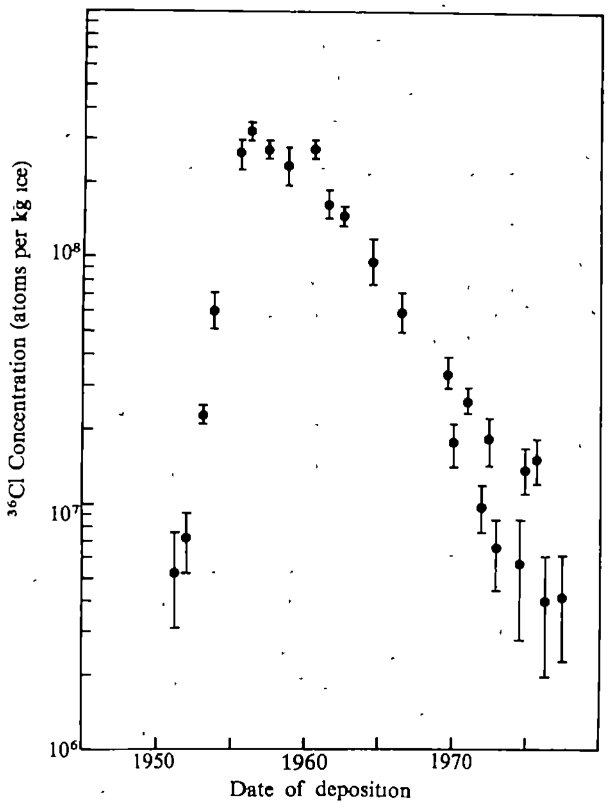

Fig. 1 The ^{36}Cl profile in an ice core drilled at Dye 3, Greenland, showing the large pulse that resulted from activation of ^{35}Cl during marine nuclear weapons tests. The age scale was determined by counting the seasonal variations in δ ^{18}O.

measurements in polar ice[7,8] is a new Cs sputter ion source[9] designed specifically for tandem accelerator mass spectrometry. This source produces a high negative ion current (10–20 μA) with improved stability. For this project the quantity of carrier was kept small (final weights ranged from 0.5 to 1 mg Cl) to ensure that the ^{36}Cl/Cl ratios before and after the bomb pulse would be well above background levels. Even with the new ion source these small samples caused some difficulties with beam stability. This is reflected in the quoted 1σ uncertainties (Table 1) which range from 5 to 50% and are generally larger than statistical errors. The background level for this run was fairly high and variable because of contamination during the sample preparation or loading and/or cross contamination during the measurements. The addition of more carrier to reduce the ^{36}Cl/Cl for the samples at the deposition peak would have alleviated these problems. From the experience gained in this run and others[7] we feel that 3–5% errors are possible with 2–3 mg Cl samples and that 1-kg ice samples should be adequate for measuring pre-bomb ^{36}Cl in polar ice cores.

The results given in Table 1 and Fig. 1 are expressed as atoms of ^{36}Cl per kg of ice and have not been corrected for the variable precipitation rate (Table 1). The ^{36}Cl/Cl ratios were reduced by the background value, which ranged from 70 to 200×10^{-15}, and were normalized to an NBS standard. The results show that ^{36}Cl concentrations at Dye 3 increased by a factor of more than 100 from pre-bomb levels. From 5×10^6 atoms per kg-ice in 1950, concentrations increased rapidly to 300×10^6 atoms per kg-ice in 1955 and then held that level until about 1960. Between 1960 and 1970 the ^{36}Cl decreased exponentially with a mean life of about 3 yr. Because of the high background and the lack of data points before 1950 we can only give an upper limit of 5×10^6 atoms kg^{-1} for the pre-bomb production rate for cosmogenic ^{36}Cl.

The integral of the ^{36}Cl bomb pulse (Fig. 1), when multipled by an average accumulation rate for Dye 3 (ref. 10) of 50 g cm^{-2} yr^{-1}, gives a total fallout at Dye 3 of 1.3×10^8 atoms cm^{-2}. This will now be compared with an estimate of the ^{36}Cl produced in oceanic tests and transported to Greenland. Table 2 lists the marine tests with a yield over 1 Mton that have been published[11–13], although we have not included the seven bombs >1 Mton detonated by the UK at Christmas Island (2° N, 127° W) during the Grapple series of tests because these were small air bombs whose contribution of ^{36}Cl to the strato-

sphere was probably quite low. Also, the large USSR tests at Novaya Zemlya Island (75° N) during 1960–61 were not included. It is not known if these test sites were near the ocean, or whether they were air or surface tests. They do not appear to have contributed in a significant way to the total ^{36}Cl. The contribution of ^{36}Cl from surface tests would not be significant since the Cl content of soil and rock is two orders of magnitude less than that for seawater.

Assuming that 2×10^{26} neutrons are produced per megaton[14], that half of the bomb neutrons enter the water, and that 32% of the neutrons that enter the water produce ^{36}Cl (ref. 15), we obtain the total ^{36}Cl produced from each premoratorium test (Table 2, column 5). For the simplest calculation, we can assume that all of this ^{36}Cl (85 kg) enters the stratosphere and is deposited uniformly over the Earth. This results in a global average deposition of 2.8×10^{8} atoms cm^{-2}. This calculated accumulation is about a factor of two higher than our measured value at Dye 3. It is, however, well documented that the distribution of fallout is not globally uniform. Measurements of ^{90}Sr deposition between 1958 and 1966 show that the deposition rate between 60° N and 70° N is actually 1.3 times lower than the global average[16]. Correction for this nonuniformity reduces the discrepancy between measured and calculated ^{36}Cl deposition to less than a factor of two. We consider this to be excellent agreement since: (1) some of the ^{36}Cl produced may not enter the cloud; (2) ^{90}Sr may have a different particle size distribution from ^{36}Cl, (3) a site dependence of fallout within Greenland of a factor of two has been observed[3], and (4) the effect of precipitation rate has been ignored.

Our Dye 3 result can also be compared with measurements of ^{36}Cl in rain and groundwater from the mid-latitudes. The ^{36}Cl deposition rate measured[1] in Long Island, New York rain collected during the bomb peak (1957–60), when corrected[17] for the precipitation rate, is 2.3 atoms cm^{-2} s^{-1}. A recent measurement of ^{36}Cl in groundwater from Ontario, Canada[17] gave a peak value of 4.8 atoms cm^{-2} s^{-1}. Our result for Dye 3, 0.5 atoms cm^{-2} s^{-1}, is a factor of 5–10 lower than these mid-latitude values. This is probably due to a combination of the latitude dependence of the stratospheric fallout and the additional contribution from direct tropospheric fallout from the Northern Hemisphere tests at lower latitudes.

The predicted mean lifetime of ^{90}Sr in the stratosphere using the model of Peterson, which takes into account the altitude and latitude of injection, is about 2 yr. This value is somewhat less than our measured value of ~3 yr for ^{36}Cl. Although this discrepancy may not be significant (an exponential with a slope of 2 yr is almost within the error bars) possible explanations are (1) contributions from additional tests during the period 1960–70 of which we are unaware and (2) fractionation between Cl and Sr in the transport out of the stratosphere.

After the Limited Test Ban Treaty in 1963, there were several smaller atmospheric tests listed in Table 2. Because these tests were smaller, higher above the ocean, and in the Southern Hemisphere their contribution to the total anthropogenic ^{36}Cl is small and hard to estimate accurately. However, they may be the cause of the small peaks seen in the data in the early 1970s.

It may be possible to use variations in the production of cosmogenic ^{36}Cl to study past solar activity as seen through the Sun's modulation of the galactic cosmic ray flux. The atmospheric residence time for ^{36}Cl is much less than that for ^{14}C so that time resolution should be better and amplitude variations should be larger. Our upper limit for pre-bomb ^{36}Cl fallout is 8×10^{-3} atoms cm^{-2} s^{-1} which is consistent with predictions[18,19] of $1\text{–}3\times10^{-3}$ atoms cm^{-2} s^{-1}. Further measurements with older ice are planned.

We thank Fred Phillips for useful discussions. This work was supported by NSF grant no. PHY-82-40321, California Space Institute grant no. 77–81, and the Swiss NSF.

Thermonuclear ^{36}Cl pulse in natural water

H. W. Bentley*, F. M. Phillips†, S. N. Davis*, S. Gifford*, D. Elmore‡, L. E. Tubbs‡ & H. E. Gove‡

Radionuclides produced by atmospheric testing of nuclear weapons have been used as environmental tracers for the past 30 years. ^{185}W and ^{90}Sr have proved valuable in monitoring atmospheric circulation[1], ^{14}C has been applied to oceanic mixing[2], and ^{3}H has been routinely used as a tracer in the hydrologic system. Tandem accelerator mass spectrometry[4] has made possible measurements of several long-lived radionuclides that were previously virtually undetectable. One of the potentially most valuable of these for studying the movement and mixing of groundwater and surface water is ^{36}Cl. ^{36}Cl is produced continuously in the terrestrial environment in very small amounts by spallation of argon by cosmic radiation and by the capture of naturally produced neutrons by ^{35}Cl. It was also produced in much larger amounts by neutron activation of seawater and released into the environment during atmospheric

thermonuclear tests. This ^{36}Cl pulse has many potential applications as a tracer in natural water systems. Here, numerical modelling and analyses of water samples indicate that in the mid-latitudes the fallout peak was 3 orders of magnitude above the natural background, and that the period of enhanced ^{36}Cl fallout was 1953 to about 1964.

Chloride is widely used as a natural and artificial tracer in studies of freshwater systems. In most conditions, it is negligibly sorbed on solid particles, which greatly enhances its potential value. However, the timing and size of the ^{36}Cl fallout pulse, which have not been reported previously, have to be known to make best use of the bomb ^{36}Cl as a tracer.

^{36}Cl differs from many other bomb-produced tracers in that it is neither a product of direct fission nor of fusion. Virtually all bomb ^{36}Cl originates from thermal neutron activation of ^{35}Cl. Sufficient chloride to produce measurable global ^{36}Cl fallout is present only when nuclear explosions are detonated near seawater. Thus only reported explosions on barges or small islands, of sufficient yield to penetrate the stratosphere, have been used as input to our model. Explosion data were taken from refs 5, 6. Neutron activation production in seawater has been calculated by Dyrssen and Nyman[7]. Cloud heights for some tests are published by Glasstone[8]; if not available, they were estimated according to Peterson[9].

The fallout from these stratospheric injections was simulated by means of the HASL atmospheric box model of Krey and Krajewski[10], modified to simulate global, rather than hemispheric, fallout. The model distinguishes between the stratosphere above 21 km, the stratosphere below 21 km, and the troposphere. The fallout from one to the next is considered to be a first-order rate process, with rate constants derived from ^{109}Cd and ^{90}Sr fallout data[10].

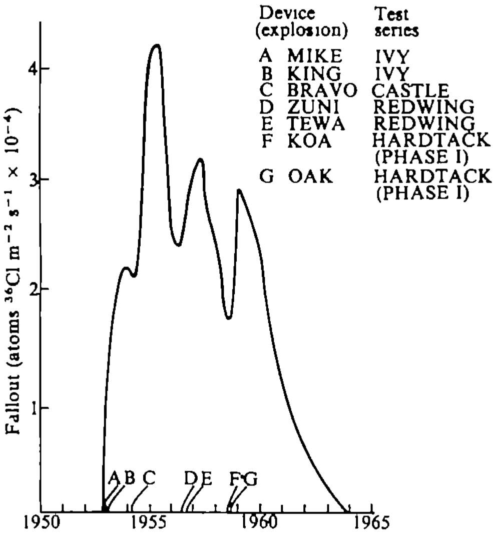

Fig. 1 Fallout of thermonuclear ^{36}Cl predicted by the atmospheric box model.

The model was calibrated using ^{36}Cl concentrations in rainfall on Long Island reported by Schaeffer *et al.*[11]. In five samples of rainwater consisting of composites collected over 2–4 week periods between 1957 and 1960, the mean fallout rate was 2.3×10^4 atoms ^{36}Cl m^{-2} s^{-1} (Table 1). The data show a wide scatter which is typical of radionuclide concentrations in rainfall. The fallout at Long Island calculated from these data was converted to global fallout according to the latitude dependence published by Peterson[9]. The model results using this calibration are illustrated in Fig. 1.

Available data on ^{36}Cl concentrations in modern water are summarized in Table 1. The water samples may be divided into four categories: (1) water collected before nuclear testing, (2) concurrent with testing nuclear devices in and near ocean water, (3) postdating the testing and (4) mixtures from different periods.

The 'pre-bomb' well waters from Spain, Arizona, and Texas have been confirmed as such by ^{3}H and ^{14}C dating but are young enough so that measurable ^{36}Cl decay would not have occurred. ^{36}Cl-to-chloride ratios of these samples conform to the geographical distribution of naturally produced ^{36}Cl fallout predicted by Bentley and Davis[12].

The only undiluted sample of ground water from the period of atmospheric nuclear testing is from a shallow Long Island well reported by Schaeffer *et al.*[11]. The ^{36}Cl concentration of this sample is close to the average for rainfall from the same period.

The San Pedro River sample is probably completely post-bomb, inasmuch as the river is largely ephemeral. The La Jolla and Tucson rainfall samples indicate that the ^{36}Cl content of present-day precipitation has returned to approximate pre-bomb levels. The remainder of the analyses are from hydrological systems which tend to mix water over long time periods, such as lakes, perennial rivers, and recharge areas of aquifers.

Although the data in Table 1 are reasonable in view of the fallout predictions, they yield little information concerning shape and magnitude of the pulse. To obtain more information, we sampled water from the Borden Canadian Forces Base landfill site in Ontario, Canada in November, 1981. The hydrogeology and geochemistry of the site, including the locations we sampled, have been thoroughly investigated[13–15]. The tritium distribution has been investigated by Egboka *et al.*[16]. We sampled vertical profiles through the 'plume' of recent recharge delineated in the cited studies. The ^{36}Cl concentrations of samples collected from nested piezometers T5-A and B and T6-A and B are given in Table 2 and the data from T5 are illustrated in Fig. 2. Piezometer T5 penetrates the centre of the plume, but T6, on the edge of the plume, is not expected to give a representative sampling of the fallout.

Table 2 ^{36}Cl in groundwater from the Borden Canadian landfill site

T6B-2	19.51	0.35±0.04

Owing to uncertainties in the flow patterns, the sample depth cannot be definitely correlated with the date of recharge. However, the shape of the pulse is similar to that predicted by the fallout model. Furthermore, the maximum ^{36}Cl concentration is three orders of magnitude above the natural concentration estimated from the precipitation, evaporation, and chloride data of McFarlane *et al.*[13] and Egboka[17] and the geographical distribution of ^{36}Cl/Cl in pre-1953 water estimated by Bentley and Davis[12]. The magnitude of this peak agrees with that of the fallout peak predicted on the basis of Krey and Krajewski's model and calibrated with Schaeffer's data. The maximum fallout rate calculated using the figures from the Borden site is 4.8×10^4 atoms ^{36}Cl m^{-2} s^{-1}, compared with the predicted maximum of 4.2×10^4 atoms ^{36}Cl m^{-2} s^{-1}. The total amount of ^{36}Cl in the vertical profile is 5.75×10^{12} atoms m^{-2}, whereas the total fallout predicted by the models is 7.1×10^{12} atoms m^{-2}.

Some preliminary data have also been obtained from an ice core sample at the Dye 3 site in Greenland[18]. The timing and

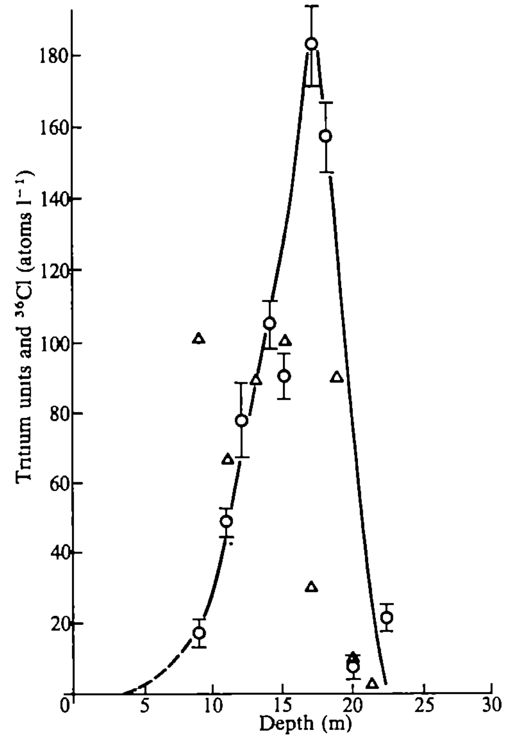

Fig. 2 ^{36}Cl (×10^7, ○) tritium 16 (△, error ±10 tritium units) concentrations in ground water from the Borden Canadian Forces Base landfill in Ontario, Canada. Data for T-5 nested piezometers are plotted.

the general shape of the peak are similar to that shown in Fig. 1, but the maximum concentration is only 80 times the minimum. This contrasts with the 900-fold difference shown in data of Table 1. The contrast could be due to the fact that minimum values measured in the ice may be above background or due to the latitudinal dependence of the fallout. For example, fallout of ^{185}W from the Hardtack series of explosions in the Pacific (which were major ^{36}Cl-producing tests) was more than an order of magnitude greater at 40° N than at 64° N (ref. 1).

We conclude that data obtained thus far are consistent with the ^{36}Cl fallout predictions and that the pulse lasted from 1953 to 1964. In contrast with ^{14}C and tritium, ^{36}Cl fallout rates have returned to levels existing before thermonuclear testing. In the mid-latitudes, the bomb pulse peak height was about 1,000 times the natural background level.

^{36}Cl pulse characteristics appear to be well suited for use as an environmental tracer. The maximum fallout rate was large enough to be unequivocally distinguished from natural concentrations, even after substantial dilution with stable chloride from natural systems. ^{36}Cl is one of the few hydrophilic anthropogenic tracers which has returned to natural levels since the time of the maximum input. This characteristic should be particularly valuable in the study of hydraulic flow and dispersive mixing. Decay of radionuclides and dispersive mixing of ground water create decreases in concentration which are difficult to distinguish. The long half life of ^{36}Cl should eliminate such ambiguities in interpretation of the bomb pulse. We expect that in the near future bomb-produced ^{36}Cl will usefully supplement bomb tritium as an environmental tracer, and that, as the bomb-tritium pulse decays to background levels, ^{36}Cl may eventually replace it.

We thank Peter Fritz and Robert Drimmie of the University of Waterloo for help and advice in sampling the Borden site. This research was funded by the Office of Nuclear Waste Isolation under grant ONWI-E512-04900 and the NSF under grant PHY-82-40321.

The evolution of propagating rifts

Dan McKenzie

Bullard Laboratories, Department of Earth Sciences,
Madingley Rise, Madingley Road, Cambridge CB3 0EZ, UK

The magnetic survey carried out by Mason and Raff[1,2] off the north-west coast of the US has been central to the development of many of the concepts of seafloor spreading and plate tectonics. Recently Hey and Wilson[3] have again used this survey to illustrate Hey's suggestion[4] that ridge segments sometimes increase their length by propagation. This process leads to a characteristic pattern of magnetic anomalies offset by discontinuities which Hey called pseudofaults because, unlike fracture zones, they (Fig. 1) were never plate boundaries. We demonstrate here how the geometry of the pseudofaults, magnetic anomalies and the failed rift can be worked out using velocity triangles and the concept of stability. This method was originally developed to understand the evolution of triple junctions between three plates[5].

Hey's[4] suggestion is illustrated in its simplest form in Fig. 1*a*. The plate boundary between plates A and B, moving without rotation, consists of two ridge segments normal to the slip vector between the plates and which spread symmetrically with half rate v. The transform fault which joins them is not stationary in a frame of reference fixed to A or B, but moves in the direction shown with a constant velocity V. This behaviour causes rift 1 to increase in length, rift 3 to decrease, and generates a complicated pattern of magnetic anomalies. Though it is possible for ridges and trenches also to move at right angles to their strike, the effects of such motion are geometrically less interesting and are easily analysed. In the case of ridges such motion leads to asymmetric spreading, whereas with trenches it leads either to consumption of both plates or to generation of new plate, presumably by back arc spreading. Whether the real behaviour of a propagating rift will be as simple as that illustrated in Fig. 1*a* is not clear. Analogue experiments with wax[6] suggest that the deformation between the rifts may be distributed, rather than confined to a single boundary, and that rotation may also be important. Such possibilities are, however, ignored here, and the discussion of the evolution is restricted to the simple two plate problem.

Figure 1*b* shows the representation of Fig. 1*a* in velocity space. Since plates A and B both move rigidly they can be represented by two points separated by a distance $2v$. The mid point of the line joining these two points corresponds to one frame of reference in which the ridge axes do not move. Furthermore any frame corresponding to points on the line marked ab$_1$, ab$_3$ passing through this mid point and drawn parallel to the axis also leaves the ridge axes stationary because they are straight. Similarly lines ma and mb correspond to frames in which the magnetic anomalies on plates A and B respectively are stationary. As the transform fault is moving with respect to both plates, it is stationary in any frame corresponding to a point on line ab$_2$, parallel to the line joining A and B but a distance V from it. It is now straightforward to construct the geometry produced by the motions in Fig. 1*a*. Unlike the corresponding problem involving three plates, the two plate system cannot be unstable. The point where the lines ab$_1$, ab$_3$ and ab$_2$ intersect, marked P, corresponds to the frame in which the plate boundary system in Fig. 1*a* is stationary. Hence all points on A will move in the direction PA in this frame, those on B in the direction PB. Hence the traces of the tips of ridges 1 and 3 will be straight lines passing through the ridge tips, parallel to directions PA and PB, shown as dotted lines in Fig. 1*b*. Hey and Wilson[3] refer to the two lines passing through the tip of ridge 1 as pseudofaults and that through the tip of ridge 3 as a failed rift. The geometry of the magnetic anomalies is slightly more difficult to construct. Because the motion of the transform fault is continuous, the region between the pseudofault and the failed rift on plate B must contain continuous anomalies. These are being lengthened by new material added to B from A by the movement of the fault. The magnetic anomalies on plate A and the transform fault are both stationary where the lines marked ma and ab$_2$ intersect at the point M_a in Fig. 1*b*. All points on plate B, including the material added to B by the movement of the fault, must move in the direction of the line M_aB, which is therefore the strike of the magnetic anomalies formed by the transfer of material onto B. The pattern of magnetic anomalies can then be drawn. The resulting

0028-0836/82/510740—02$01 00

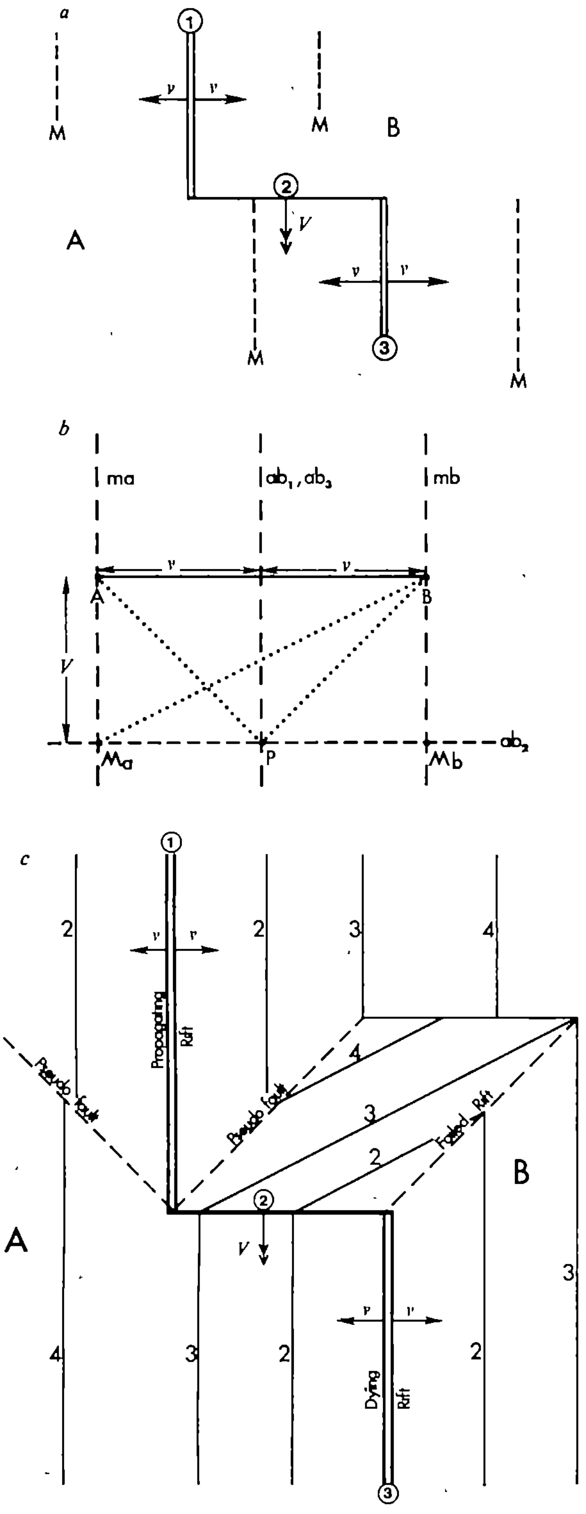

Fig. 1 *a*, Two plates A and B are separating with velocity $2v$ along a plate boundary consisting of two ridges joined by a transform fault. This fault moves with velocity V in the direction shown relative to both plates. *b*, The geometry in velocity space, with dashed lines representing frames in which features remain stationary. For instance any moving frame with a velocity on ma leaves the geometry of the magnetic anomaly M on A unchanged. The pattern of magnetic anomalies produced by these motions is shown in *c*.

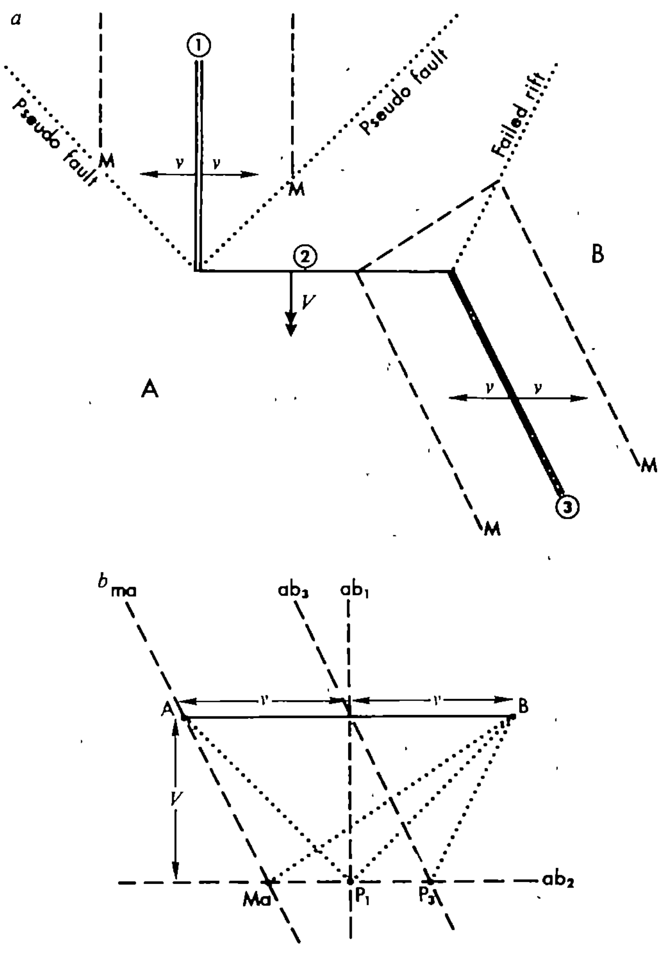

Fig. 2 *a*, As for Fig. 1, but with oblique spreading on one of the ridge segments. *b*, The geometry in velocity space.

arrangement agrees with that shown by Hey *et al.*[7]. Also shown in Fig. 1*c* is the relationship of the anomalies formed by the propagating rift to the anomalies older than anomaly 3 formed by the same rifts when they were not propagating.

Hey's original discussion was concerned with a more complicated geometry than that shown in Fig. 1*a* because one of the ridges involved was spreading obliquely, though still symmetrically. In such conditions it is probable that the ridge which is not spreading obliquely will be the one which propagates, and this geometry is shown in Fig. 2. The evolution may be worked out in exactly the same way as before. Since the two ridges are not parallel, ab_1 and ab_3 intersect ab_2 in different places, P_1 and P_3. Therefore there is no frame in which all three boundaries remain stationary. The tips of the two ridges are separating with a velocity given by the length of the line joining P_1 to P_3, and the pseudofault on plate B is not parallel to the failed rift. Hence the geometry in Fig. 2*a* can be formed by propagation from a ridge axis with no transform fault, provided part of the ridge is spreading obliquely[4]. The strike of the magnetic anomalies produced by the transfer of material from A onto B is parallel to M_aB in Fig. 2*b* as before. Further complications such as asymmetric spreading can easily be included in these constructions.

Hey and his colleagues[3,4,7] have convincingly argued that the magnetic anomalies off the coasts of Oregon and Washington are cut by pseudofaults. What is, however, less clear is whether the anomalies formed by the transfer of material from one plate to another by the movement of the transform fault can be recognized. Detailed surveys of areas where rifts may be propagating are required.

I thank R. Hey and T. Atwater for suggesting improvements to this argument.

Gabbroic rocks from the Mathematician Ridge failed rift

David A. Vanko & Rodey Batiza

Department of Earth and Planetary Sciences,
Washington University, St Louis, Missouri 63120, USA

Plutonic rocks from the ocean crust provide direct evidence on the petrological processes leading to its formation and evolution. The nature of such rocks is important for interpreting the origin of on-land ophiolites. So far, oceanic plutonic rocks have been mainly recovered from slow-spreading ridges and their associated fractures[1–13] and from trenches[14,15]. Here we report the results of petrological studies of a suite of gabbros and related plutonic and volcanic rocks dredged from the Mathematician Ridge (MR), which was a fast-spreading ridge (43 mm yr^{-1}) until it was abandoned ~3.5 Myr ago[16]. Textures and mineral chemistry of the rocks together with structural considerations indicate that before abandonment the MR produced fractionated mid-ocean ridge basalt (MORB) and fractionated gabbros. The gradual decrease of spreading rate during abandonment resulted in morphological change, eruption of more primitive MORB and possibly tectonic emplacement of the older ferrogabbros. Alternatively, the latter could have been tectonically emplaced after abandonment.

The MR failed rift consists of a series of short (~50 km) *en echelon* troughs, offset by failed transform faults[16]; its present morphology (Fig. 1) is very similar to that of slow-spreading ridges like the Mid-Atlantic Ridge[17,18] and the Mid-Cayman Rise[19] although magnetic anomalies indicate that before abandonment it was a fast-spreading (43 mm yr^{-1}) ridge[16]. Two dredges of the upper portions of the trough walls (Fig. 1) recovered cumulate gabbro, isotropic gabbro, serpentinized peridotite, diabase, and MORB lavas. Many samples are extremely fresh but most are deformed and metamorphosed or brecciated.

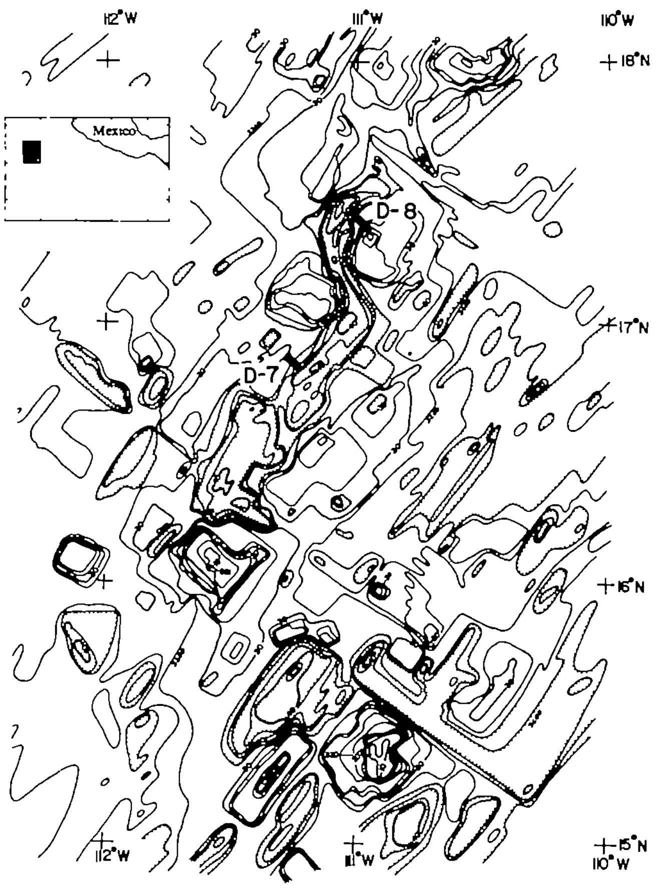

Fig. 1 Bathymetric map (contour interval 200 m) of part of the Mathematician Ridge. Locations of the two dredges that recovered plutonic rocks are shown as solid bars.

Examination of 67 thin sections and microprobe mineral analyses of about 20 representative samples are summarized in Tables 1 and 2 and Fig. 2. The fresh troctolite and other cumulate gabbros have typical cumulate textures, including foliate plagioclase tablets and centimetre-scale mineral layering. Other fresh gabbros have isotropic texture and lack mineral layering. Secondary alteration of these fresh rocks consists only of weak uralitization of pyroxenes (<1%) and very rare

Table 1 Petrographic data for Mathematician Ridge plutonic rocks

Rock type	Troctolite	Cpx gabbro	2-PX Gabbro	Metagabbro	Amphibolite	Breccia

Textures	Fresh cumulate plag laths (<6 mm); interstitial cpx and ol oikocrysts; opx rims on ol	Fresh, plag lath (<6 mm) mildly foliate, with cpx oikocrysts (<20 mm)	Cumulate plag (<7 mm) and opx (<4 mm) with interstitial cpx; slight uralitization	Mylonitic, relict igneous textures, albite veins in plag	Decussate aggregate of hb; mild foliation of opaques; interstitial clay clots	Single- and multi-crystal clasts, subrounded, poorly sorted, cemented by clay-amph matrix
Deformation‡	A	ABC	ABC	CDEF	DF	BG

Accessories not tabulated (all <1%) are epidote, prehnite, quartz, sphene, apatite, analcime; observed exclusively in metagabbro, amphibolite, and breccia, or rarely in late veins through fresh gabbro. Note that as plag becomes more albitic, opx and cpx become more iron-enriched. Metagabbro has cpx similar to that in fresh gabbro, but plag more sodic than in gabbro. Amphibolite has only albite plag, and no cpx. Breccias are inferred to be brecciated gabbro that preserve primary plag and cpx compositions.

* Pyroxene compositions given in terms of molar components wollastonite ($CaSiO_3$), enstatite ($MgSiO_3$), and ferrosilite [(Fe, Mn) SiO_3].

† Plagioclase compositions give range of normal zoning of plagioclase laths. Discontinuous anorthite-rich rims, present in the fresh troctolite and gabbros, are not included.

‡ Deformation styles observed in this rock type A, none except inclusion planes that appear to be healed fractures; B, bent pyroxene lamellae; C, stress-induced plagioclase twins and wavy extinction; D, shear bands, augen, porphyroblasts; E, 'mortar' texture; F, quartz–epidote fracture fills; G, brecciation.

Analyses: (1–2): electron microprobe analyses of representative orthopyroxene and clinopyroxene in a 2-PX gabbro (8–16). Other orthopyroxenes in 8–16 show some variation in iron content (up to ±3 mol % Fs component). (3). Average and 1σ standard deviation of eight analyses of a 4-mm hornblende porphyroblast in 7–43 amphibolite. FeO^T represents all iron as Fe^{2+} (4): Core of a small (<1 mm) decussate-textured hornblende in 7–43. Such low-Al cores are zoned to rims that resemble the porphyroblast analysis (3) (5): Brown hornblende from 7–37 metagabbro (6): 0.01 mm thick blue-green amphibole zone that flanks a tiny fracture through the brown hornblende in analysis (5) (7–37) ND, not determined

serpentinite pseudomorphs of olivine crystals. However, the rocks contain evidence of anhydrous subsolidus reactions such as exsolution of pyroxene pairs whose compositions indicate equilibrium temperatures of 896–967 °C (ref. 20) and exsolution of Fe–Ti oxide rods and flakes from plagioclase. Furthermore, plagioclase (An_{82-50}) is often rimmed by discontinuous symplectic anorthite–augite growths or has simple anorthite (to An_{92}) rims (a feature also noted in other cumulates, see ref. 21). Similar textures may form by cotectic crystallization in interstices[21,22], but in Mathematician rocks, small inclusions of anorthite plus pyroxene (either low or high Ca types) plus Fe–Ti oxide occur within plagioclase. This suggests that the anorthite did not crystallize from a silicate liquid.

The olivine and pyroxenes in the fresh gabbros are fractionated (Fe-rich, see Table 1 and Fig. 2) relative to compositions of these minerals in many other oceanic gabbros. They are similar to the most fractionated ones in gabbro from the Mid-Cayman Rise[19], and are more fractionated than practically all the same minerals from DSDP site 334 near the Mid-Atlantic Ridge[4]. The degree of differentiation of the Mathematician magma can be estimated using analysed olivines and Fe–Mg distribution coefficients: If $K_D = 0.30$ (ref. 23) then the range of magma Mg numbers ($Mg/Mg+Fe^{2+}$) was 42–50, based on the range of measured olivine compositions Fo_{71-77}. Olivine compositions from other oceanic gabbros indicate that, if the olivines were cumulus phases and $K_D = 0.30$, the liquids had the following Mg numbers: Mid-Cayman Rise, 41–69 (ref. 19); DSDP site 334, 65–67 (ref. 4); Kane Fracture Zone, 45–67 (ref. 8); Mariana Trench, 49–63 (ref. 15). From the low Mg numbers and the absence of Mg-rich samples (Mg number >50) in the Mathematician suite, it seems probable that these cumulate and isotropic gabbros formed while the MR was spreading rapidly[24–26].

In fresh Mathematician gabbros, the mafic minerals generally become more Fe-rich as coexisting plagioclase cores become

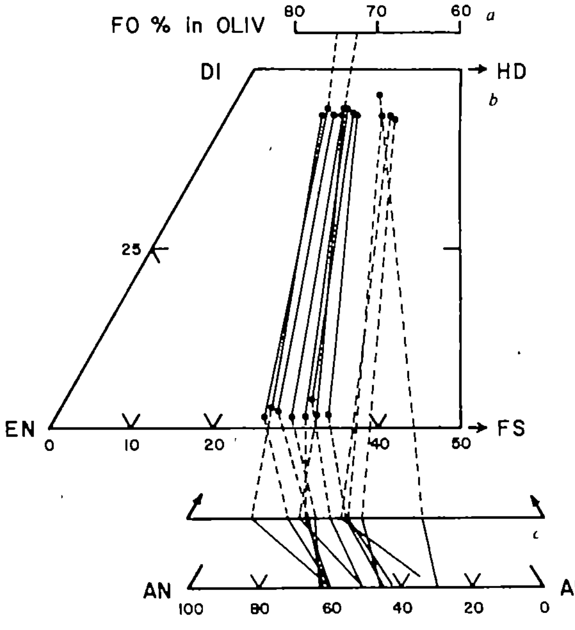

Fig. 2 Plot of electron microprobe analyses of minerals in plutonic rocks. *a*, Average olivine compositions in the two troctolite samples. *b*, Pyroxenes plotted in the conventional pyroxene quadrilateral (molar). The points are average compositions except for two (8–22 and 8–15) which are the most magnesian pairs of a small but detectable (6 mol % Fs component in cpx) intrasample variation. *c*, Molar plagioclase compositions in the Ab–An–Or ternary. Upper ternary represents the most calcic core in the sample, and lower ternary represents the most sodic rim. Discontinuous anorthitic rims (see text) are not plotted Dashed lines connect analyses from the same sample.

more albitic (Table 1, Fig. 2). This suggests that the gabbros originated from multiply-saturated basaltic liquids undergoing slow cooling and fractional crystallization with some crystal settling contributing to the formation of cumulate gabbros.

Most gabbros from the MR are deformed and the extent of deformation is generally correlated with the extent of alteration/metamorphism of primary phases, except in brecciated rocks. These were apparently brecciated by brittle fracturing at low temperature, and contain chiefly clays as secondary minerals. In contrast, most deformed gabbros contain higher temperature metamorphic assemblages (see Tables 1 and 2). A continuous gradation from fresh gabbro to completely amphibolitized gabbro occurs among MR samples. This transformation is characterized by: (1) increase in the abundances of Cl-bearing amphibole (Table 2) at the expense of pyroxenes, and (2) concomitant decrease in the anorthite component in plagioclase: in completely amphibolitized gabbros, the scant plagioclase is albite, which may be retrograde. Additional evidence for retrograde metamorphism in the amphibolitized gabbros includes the presence of epidote (for example, Ps_{15-25} in sample 8-24; Ps_{14} in 8-17), prehnite ($Fe_2O_3 < 0.8$ wt% in samples 8-1, 8-18), albite veins, tremolite ($Trem_{66}Act_{34}$ in sample 8-16, $Trem_{62}$ in 8-24), chlorite, analcime, and quartz and quartz + Ep veins that cut foliation. The quartz veins contain polyphase fluid inclusions which sometimes contain a salt crystal. These inclusions and the Cl content of amphiboles indicate that late hydrothermal fluids were quite saline[11,27].

The serpentinite (82% talc/serpentine, 2% spinel, 16% clay and amphibole) contains Al = rich Cr-spinels [$Cr/Cr+Al = 0.4$; $Fe^{3+}/Fe^{3+}+Al+Cr = 0.01$; $Mg/Mg+Fe^{2+} = 0.64–0.70$] that have very rare inclusions of olivine (Fo_{91}). The spinels form coarse amoeboid grains, similar to a texture inferred by Dick[28] to occur characteristically in peridotite that has been partially melted. By contrast, cumulate spinel grown from a melt is normally euhedral[28]. Therefore, textural evidence, together with the Al-content of the Cr-spinel, suggests that the serpentinitized peridotite represents partially-melted oceanic upper mantle material. Altered diabase recovered in dredge 8 contains secondary albite but relict clinopyroxene ($En_{51}Fs_{11}$) and is relatively unfractionated with $TiO_2 = 1.05$ wt%, Cr = 370 p.p.m., La = 2.68 p.p.m. and $(La/Sm)_N = 0.58$ (ref. 29 and work in preparation). Most of the MORB lavas recovered are also relatively unfractionated. Those from dredge 7 have Mg number = 74, MgO = ~10 wt%, $TiO_2 = 0.72$ wt%, Cr = 500 p.p.m., Ni = ~200 p.p.m., La = 1.0 p.p.m. and $(La/Sm)_N = 0.35$, while the most fractionated one, a MORB lava from dredge 8 has Mg number = 65, $TiO_2 = 1.28$ wt%, Cr = 270 p.p.m.

Plutonic rocks recovered in the MR are broadly similar to other oceanic gabbros, but they comprise a relatively fractionated suite. Detailed differences such as a lack of cumulus spinel, which is present in DSDP site 334 cumulates[4], will be considered elsewhere. The suite of volcanic and plutonic rocks from the MR is similar to that found in ophiolites[30]. However, because both dredges in MR troughs contained all rock types, we have no constraints on stratigraphical thicknesses, or even whether an orderly stratigraphy is exposed. If there is an orderly stratigraphy, then oceanic crust at the MR is very thin (<600 m, from Fig. 1). Otherwise, processes such as tectonic disruption or diapiric rise of serpentinite may have occurred. The chemical contrast between unfractionated MORB lavas and diabase and the relatively fractionated gabbros might suggest that these rocks are in tectonic contact, and gabbroic breccias that formed at low temperature may have resulted from such tectonism. The timing of the presumed tectonic activity is poorly constrained, but some could have postdated the cessation of spreading and the inferred morphological changes associated with gradually decreasing spreading rate of the MR. We favour the notion that fractionated gabbros originated while the MR was spreading rapidly, whereas less fractionated MORB lavas were produced during the transition of the MR to its present slow-spreading morphology, because this is consistent with petrological and geophysical data for presently active slow and fast-spreading ridges[24–26]. Choosing between this hypothesis and the possibilities discussed above will require further detailed studies of the MR and the stratiagraphical/structural relationships of the rocks exposed there.

We thank the master and crew of the RV *Velero IV* for assistance, also the NSF (grant OCE 8004244) and the ONR for financial support and J. Mammerick, R. Hey, P. J. Fox, and T. Grove for helpful comments.

Why is Mrs Thatcher interrupted so often?

If a conversation is to proceed smoothly, the participants have to take turns to speak. Studies of conversation have shown that there are signals which speakers give to inform listeners that they are willing to hand over the conversational turn[1–4]. Some of these signals are part of the text (for example, completion of syntactic segments), some are non-verbal (such as completion of a gesture), but most are carried by the pitch, timing and intensity pattern of the speech; for example, both pitch and loudness tend to drop particularly low at the end of a speaker's turn. When one speaker interrupts another, the two can be said to be disputing who has the turn. Interruptions can occur because one participant tries to dominate or disrupt the conversation. But it could also be the case that mistakes occur in the way these subtle turn-yielding signals are transmitted and received. We demonstrate here that many interruptions in an interview with Mrs Margaret Thatcher, the British Prime Minister, occur at points where independent judges agree that her turn appears to have finished. It is suggested that she is unconsciously displaying turn-yielding cues at certain inappropriate points. The turn-yielding cues responsible are identified.

Mrs Thatcher's interviews display a distinctive pattern—she is typically interrupted more frequently than other senior politicians, and she is interrupted more often by interviewers than she herself interrupts[5]. This pattern is consistent across a wide variety of interviewers (including Denis Tuohy, Brian Walden and Llew Gardner) and across a wide variety of topics[6]. Butting-in interruptions are particularly common in her interviews. These occur where her interviewer interrupts but fails to get the floor, as in the following example where Denis Tuohy (D.T.) tries to take the floor from Mrs Thatcher (M.T.) (*TV Eye*, April 1979).

M.T.: . . . if you've got the money in your pocket you can choose/whether you spend it on things which attract Value Added Tax/or not
D.T.: (You s-
(
M.T.: (and the main necessities don't
D.T.: You say a little on Value Added Tax

(word 1
(word 2 indicates simultaneous speech

A series of experiments was designed to test the hypothesis that Mrs Thatcher is often interrupted because she displays turn-yielding cues at points where she has not completed her turn. Forty extracts were selected from the Denis Tuohy *TV Eye* interview (ITV, April 1979): 10 were turn-final (that is, utterances at the end of a turn immediately preceding a smooth speaker-switch), 20 were turn-medial (utterances from within a turn), and the remaining 10 were turn-disputed (utterances immediately preceding an interruption by Tuohy). These extracts all contained at least one sentence. The extracts were presented to subjects who had to judge whether Mrs Thatcher's turn was complete or not, in a forced choice procedure. The extracts were presented on video to 79 subjects, on audio only to 29 subjects (in the audio presentation, only the final tone group of each utterance was presented, with two exceptions in which the last two tone groups were played because the final tone group comprised only one word), on vision only to 14 subjects, and typescripts of the extracts were presented to 20 subjects. There were different numbers of subjects in conditions because the extracts were presented in university classes. All subjects were students at the universities of Sheffield or Sussex. For each of the 40 extracts in each of the 4 modes of presentation, the percentages of completion judgements were calculated (see Table 1).

Table 1 Results of completion–judgment experiments to assess the reasons Mrs Thatcher is interrupted so often

Mean percentage of utterances judged to be complete

	Mode of presentation			
	Video	Vision only	Audio only	Typescript
Turn-final	83.530	76.430	62.230	63.500
Turn-disputed	40.120	38.570	55.860	50.500
Turn-medial	23.045	18.570	32.405	58.250

Correlations between presentation modes (% completion judgements for each utterance)

Vision only	Audio only	Typescript	
0.898	0.676	0.083	Video
	0.586	0.000	Vision only
		−0.080	Audio only

An analysis of variance (ANOVAR) revealed that both 'type of utterance' ($F = 23.265$; $P < 0.0001$) and 'mode of presentation' ($F = 8.282$, $P < 0.0001$) significantly affected judgements of completion. There was also a significant interaction effect between type of utterance and mode of presentation ($F = 7.692$; $P < 0.001$). As predicted, turn-final utterances produced the

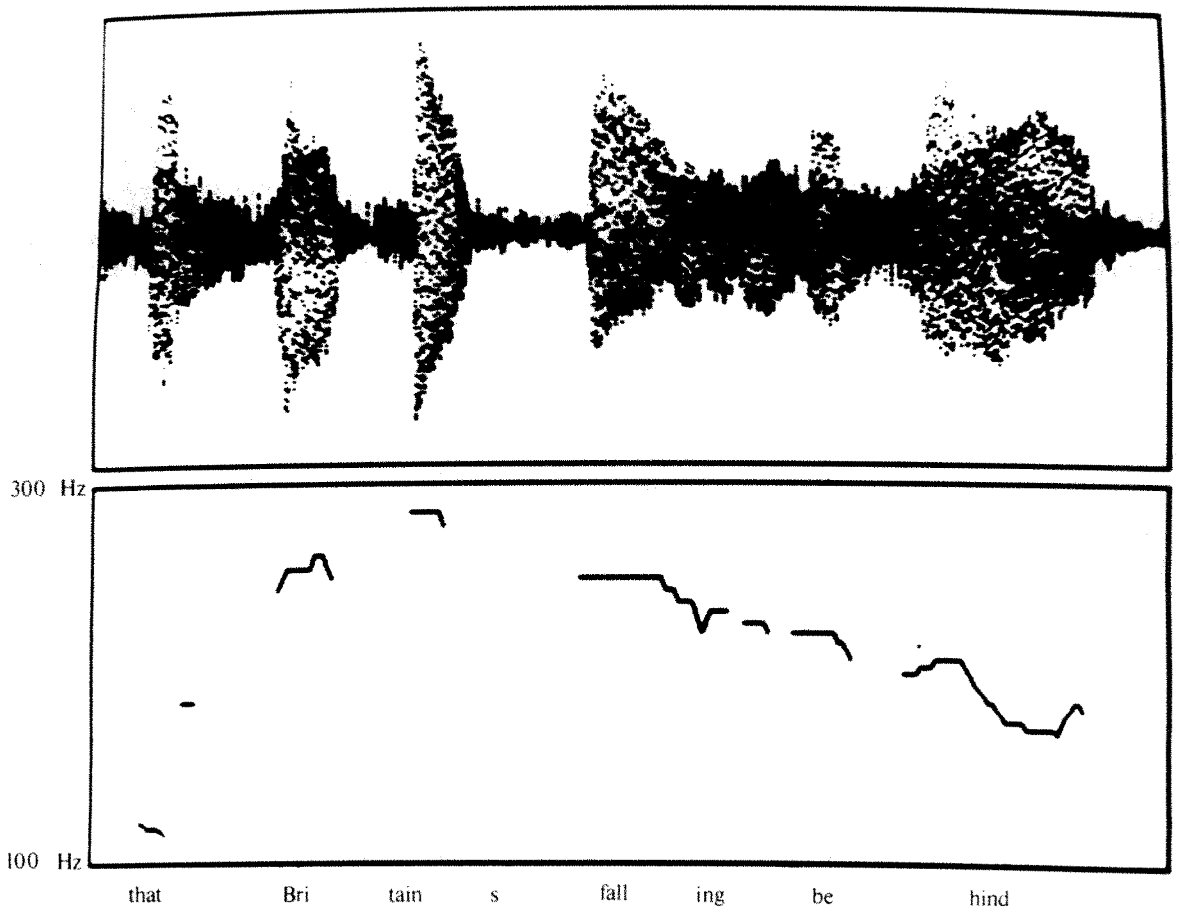

Fig. 1 Amplitude trace and pitch contour of turn-medial utterance, showing slow fall in utterance pitch.

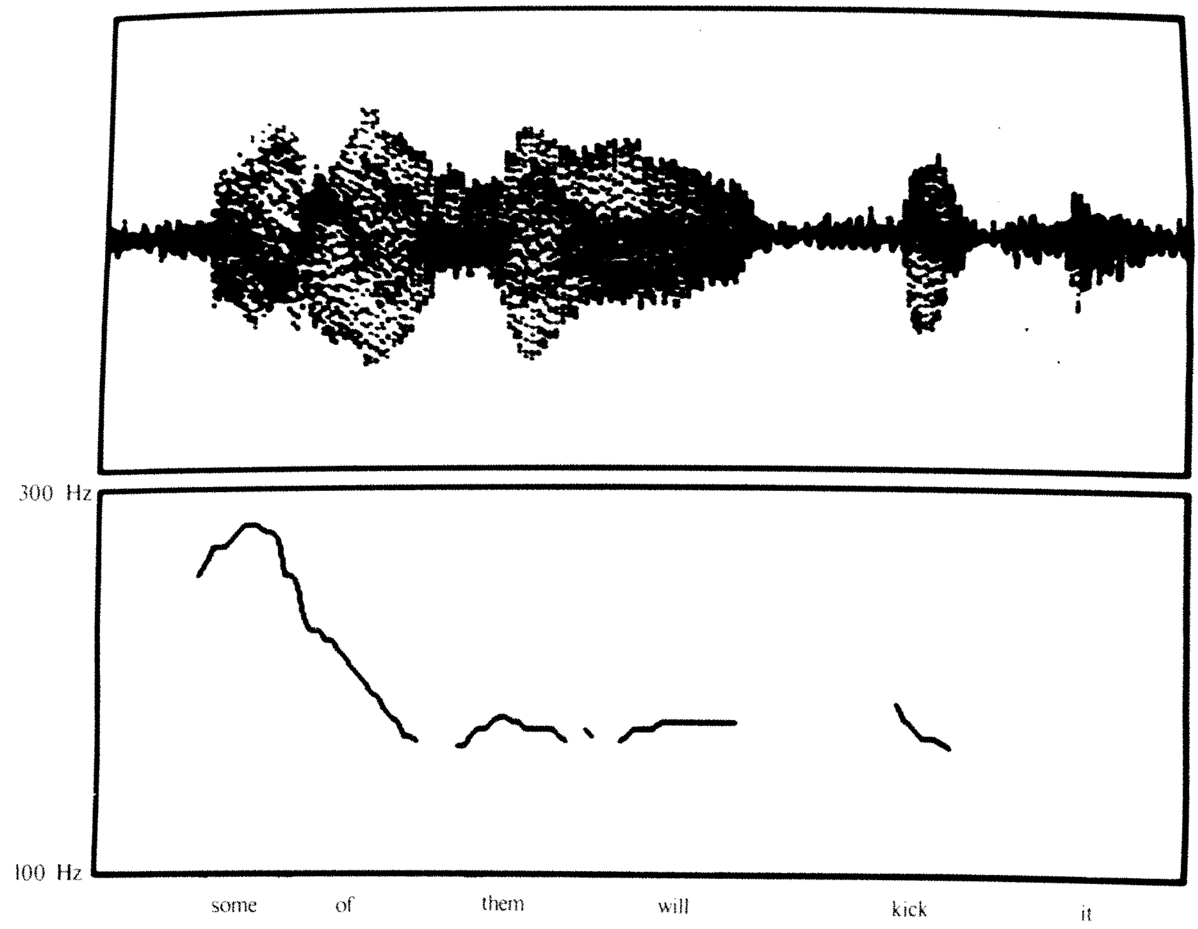

Fig. 2 Amplitude trace and pitch contour of turn-final utterance, showing fast fall in utterance pitch.

most completion judgements, and the turn-medial the lowest, with the disputed turns falling somewhere in between these two. One-factor ANOVARs revealed that 'type of utterance' had a significant effect in the case of the video presentation ($F = 34.791$, $P < 0.0001$), audio presentation ($F = 5.129$, $P < 0.02$) and vision-only presentation ($F = 25.486$, $P < 0.0001$). With the typescript, however, there was no significant effect ($F = 1.185$, not significant). (Note that significant effects did emerge in conditions with smaller numbers of subjects than the typescript condition, thus in fact demonstrating the robustness of the effects.) A comparison of means, using the Tukey HSD procedure (see ref. 12, p. 87) revealed that judged completion scores were significantly higher for turn-disputed utterances than for turn-medial utterances for the video presentation ($F = 5.53$, $P < 0.05$), the audio presentation ($F = 5.15$, $P < 0.05$) and the vision-only presentation ($F = 6.09$, $P < 0.05$).

Tests for correlation revealed significant positive correlations (all at the 0.001 level or beyond) among the video, vision-only and audio-only conditions for proportion of completion judgements for each utterance. The typescript condition judgements, however, did not correlate significantly with any of the other conditions (see Table 1). Thus, although, for example, the means for the turn-final utterances in the audio and typescript conditions are similar, the individual utterance ratings which comprise the means are obviously quite different.

Thus the basic hypothesis was supported—those utterances immediately preceding an interruption by the interviewer were judged to be complete more often than turn-medial utterances and this was not on the basis of syntactic or semantic content (present in the typescript) because, of course, no significant effect emerged in the case of the typescript, but on the basis of information carried in the audio channel and in the visual channel of the interaction, as models of turn-taking such as that of Duncan[2] would predict. Subsequent analyses sought to determine exactly which signals were giving rise to subjects' perceptions of these utterances as complete.

First, the 40 extracts from the Denis Tuohy interview with Mrs Thatcher were digitized and coded into LPC (linear predictive coding) parameters, and a value for the fundamental frequency of each sample was extracted. All 40 utterances terminated in a pitch fall with one exception, a question which ended in a rise; this exception was excluded from further auditory analysis. The value of the fundamental frequency in cycles per second was determined for the highest and lowest points (peak and trough) of each terminal fall. The mean values for the three types of utterance are displayed in the first two columns of Table 2. Column 3 shows the mean pitch range covered by the fall (that is, the difference between columns 1 and 2), and column 4 gives the mean time in milliseconds over which the fall was realized.

ANOVARs on these four measures showed that on two of them, the three conditions differed significantly: (1) The trough of the fall; the difference between conditions was significant ($F = 5.75$, $P < 0.01$), and Scheffé *post-hoc* comparisons showed that the turn-final utterances ended significantly lower than the other two groups, which did not differ significantly from one another.

(2) The timespan over which the terminal fall was realized; the difference between conditions was significant ($F = 4.61$, $P < 0.02$), and Scheffé *post-hoc* comparisons showed that this effect was due to the turn-medial falls being slower than either of the other two types of utterance, which did not differ significantly (see Figs 1, 2). There was no significant difference between the three types of utterance on either the height of the pitch peak or the range of the fall.

This analysis suggests that the turn-disputed utterances may, in fact, have conflicting cues: a fast fall like the turn-final utterances, but a fall which does not descend very low, like the

Table 2 Mean peak and trough values for three types of utterance

	Peak	Trough	Δ	Span
Turn-final	238	141	97	693
Turn-disputed	263	167	96	463
Turn-medial	275	161	114	953

turn-medial utterances. This, in turn, suggests that while the speaker is actually giving a number of cues to the end of her turn, the cue which she considers paramount may be different from the cue which her interlocutor considers paramount. If she considered that her most decisive cue to the end of her turn was letting her voice drop to around 140 Hz instead of keeping it no lower than 160 Hz, whereas her interlocutor considered that her most decisive cue was a rapidly executed final fall rather than a slow fall, their respective decisions as to whether or not she had finished her turn would differ in precisely those cases which were disputed in the present sample of utterances.

One of the authors, trained in phonetic transcription, then transcribed the 40 utterances without knowledge of the position of the utterances in the speaker's turn. The transcriptions of the turn-final and turn-medial utterances were then separately inspected, and the prosodic and vocal quality features occurring in three or more of these utterances listed. Five 'final' features were found: pitch downstep (rapid drop) before the main fall (tonic); double falling contour; allegro portion before the tonic; whispery voice; and creaky voice. Three 'medial' features were found: allegro continuing through the tonic; pitch upstep before the final fall; and a non-falling sustained contour after the fall. (Note that because all our sample utterances ended in falls, we must have underestimated the complete range of cues when non-falling utterances are included. For example, many turn-medial utterances end in a fall–rise.)

The remaining utterances were then checked for the presence of these features, which were assumed to be characteristic of turn-final and turn-medial utterances, respectively. The five 'final' features occurred on average 2.2 times per turn-final utterance, but 0.2 times per turn-medial utterance. Turn-disputed utterances, with a mean of 1.6, were closer to the turn-final utterances than to the turn-medial utterances. The three 'medial' cues occurred on average 0.65 times per turn-medial utterance, but 0.10 times per turn-final utterance. Turn-disputed utterances again fell in between with a mean of 0.30.

The number of acoustic cues present in each utterance was then correlated with the results of the audio perception test, and the proportion of completion judgements for each utterance was found to have a significant positive correlation with the mean number of 'final' cues present in that utterance ($r = 0.46$, $P = 0.003$), but a significant negative correlation with the mean number of 'medial' cues ($r = -0.45$, $P = 0.004$). Thus, the listeners in this experiment seem to have been making use of these phonetic and vocal quality cues in making their forced choice judgements.

In terms of the visual channel, the main signal guiding completion judgements must have been eye gaze because, in a large proportion of instances, the camera angle was such that no information was available on other aspects of nonverbal behaviour such as gesture (gesture termination being an important turn-yielding signal, and gesture maintenance an important turn-holding signal, according to Duncan). Eye gaze has been shown in the past to be implicated in turn regulation[7–9]. Analysis of the video revealed that in 100% of the turn-final utterances, Mrs Thatcher was looking at her interviewer at the end of the utterance, compared with 55% of turn-medial utterances. Turn-disputed utterances were again intermediate with 80%.

We have argued that some interruptions in conversation may arise from the transmission of turn-yielding cues at inappropriate points rather than from any desire on the part of either participant to dominate or disrupt the conversation. It has often been suggested that conversation can be regarded as a highly skilled performance[10,11]. Successful manipulation of these very subtle turn-taking signals must certainly rank as one important aspect of this conversational skill.

We thank John Laver for advice on the voice quality analysis.

Is annual reproduction in deep-sea echinoderms a response to variability in their environment?

P. A. Tyler, A. Grant, S. L. Pain & J. D. Gage*

Department of Oceanography, University College of Swansea,
Singleton Park, Swansea SA2 8PP, UK
* Scottish Marine Biological Association, Dunstaffnage Marine
Research Laboratory, PO Box 3, Oban, Argyll PA34 4AD, UK

The deep-sea environment has traditionally been considered as one of the least variable on the surface of the Earth[1–3]. However, recent evidence[4–6] suggests that there may be a seasonal fluctuation in the physicochemical environment, and there is further evidence[7–11] that annual reproductive periodicities may occur among populations of deep-sea invertebrates. We report here evidence for annual periodicities and considerable between-species synchrony in the reproductive cycles of five deep-sea echinoderms, spawning occurring in late winter and early spring. These species also show a similar mode of early development that suggests adaptation to a seasonally varying food supply.

One of the aims of a long-term time series sampling programme initiated by the Scottish Biological Association in the Rockall Trough (north-east Atlantic)[12,13] is to test the hypothesis that annual periodicities may occur in deep-sea invertebrates. In 1975 a permanent station was established at 2,900 m depth (54°40′ N; 12°16′ W). In 1978 this station was supplemented by a second (station 'M') at a depth of 2,200 m nearer the base of the Hebridean Slope (57°18′ N; 10°23′ W). Samples of the benthic fauna have been taken from both stations, using either an epibenthic sledge or an Agassiz trawl at approximately 4-monthly intervals to the present date.

Although a wide variety of deep-sea benthic invertebrates have been collected, echinoderm species dominate in terms of biomass. Seven echinoderm species (Table 1*a*) were collected in sufficient numbers to determine any seasonal reproductive cycles. A further seven species have been examined but were collected irregularly or in insufficient numbers to determine reproductive periodicity (Table 1*b*). In addition, echinoderm material is available to us from a number of other recently obtained samples from the Rockall Trough[14], and fine-meshed rectangular midwater trawl (RMT 1; mesh diameter 0.33 mm) samples have been obtained over station 'M' to look for echinoderm larvae (Table 1*c*).

To investigate the reproductive cycle of each species, the gonads of each specimen were dissected out and processed to paraffin wax, sectioned and stained. In all species examined the sexes were separate and equal in numbers, and since gametogenesis is more easily determined in females, we use data on oocyte size frequencies (Fig. 1*a–c*) to study reproductive seasonality. The diameters of at least 100 oocytes per specimen were measured and from these data oocyte-size/frequency diagrams constructed (Fig. 1*a–c*).

* Immature, indeterminate, hermaphroditic and parasitized specimens are not included.
† Including additional material not from time series.

Among the 14 species of echinoderms (Table 1), two distinct reproductive strategies are evident. In nine of the species, a few, large-sized eggs (~1,000 µm diameter) are produced[15–17]. This is usually interpreted as indicating direct development, omitting a larval stage[18,19]. None of these species show any indication of seasonality in gametogenesis, eggs presumably being produced continuously throughout the year. The production of a few large eggs with considerable reserves of yolk is considered a result of evolutionary selection for increased efficiency of reproduction with minimal wastage of fertilized eggs, embryos or larvae before recruitment to the adult population.

An alternative reproductive strategy is seen in the remaining echinoderms examined (Table 1) and is particularly evident in *Ophiura ljungmani, Plutonaster bifrons* and *Echinus affinis*. To these three species may be added *Ophiocten gracilis* and *Dytaster insignis*. All these species produce a large number of small (~100 µm diameter) eggs which develop as free-swimming larva and feed in the plankton[18,19]. It is of great significance that these echinoderms show both between- and within-species synchrony in egg production (Fig. 1*a–c*). This is especially evident in *O. ljungmani* and *E. affinis*. In the former, gametogenesis is initiated in March/April, and gonad growth continues until maximum development is attained in November. Spent individuals are found in January and February each year. Oogenesis in *E. affinis* appears to start in the germinal epithelium of the ovary at the time of maximum development of the previous year's oogenic growth. The ripe oocytes are spawned in January/February and the newly developing oocytes within the germinal epithelium develop to reach maximum size in November/December, by which time the next cycle of oogenesis has been initiated.

In *P. bifrons* the annual oogenic cycle does not appear as discrete as that of *O. ljungmani* and *E. affinis*. Gametogenesis can occur from January to at least May. There is a period of oocyte growth before spawning, which appears to occur from November to March.

The degree of variation in gonad development, both between samples and between individuals within samples, may be determined by the analysis of oocyte size/frequency data using a mixed model, nested-design, analysis of variance[20]. The percentage of total variance, and the variance between individual

* Value in parentheses indicates degree of freedom in numerator of *F*-ratio; degrees of freedom of denominator are effectively ∞.

† *Ophiura albida* and *O. texturata* are shallow-water species included for comparison. j = % of variance between individual means explained by sample means.

mean oocyte size accounted for by the sample means is large (>60%) for *O. ljungmani, E. affinis* and *P. bifrons* (Table 2). These data are comparable with values for shallow-water species known to breed seasonally (Table 2)[21]. Highly significant variation in mean oocyte size occurs between samples within each species. By contrast, although there are significant differences in sample means for *Bathybiaster vexillifer, Hymenaster membranaceus* and *Ophiomusium lymani,* this accounts for a much smaller percentage of variance between samples (Table 2). In *Benthopecten simplex,* the sample means are not significantly different.

The values suggest that there is a distinct variation in mean oocyte size throughout the year in *E. affinis, O. ljungmani* and *P. bifrons* and confirms the observations of seasonal variation seen in the oocyte size/frequency figures.

These data indicate an annual reproductive periodicity that culminates in a spawnout of gametes in January/February each year. In addition to the evidence of seasonal reproductive cycles shown in gametogenic cycles of echinoderms, the occurrence of larvae has been followed in seasonal hauls using the RMT 1. The larval form, *Ophiopluteus ramosus*, was taken abundantly only in the spring (April to June) of each year. The spring-time occurrence of this larva has been noted for several years[22–24]. *Ophiopluteus ramosus* is now known as the larval form of *Ophiocten gracilis*[25]. This brittle star has a distribution centred on 1,000 m, where we may conclude it also shows an annual reproductive cycle.

In addition to the reproductive data, the epibenthic-sledge time series has provided evidence of a late spring/summertime recruitment of post-larvae of both *O. ljungmani* and *E. affinis*[11,26].

From these data we see that four species of deep-sea echinoderm, *O. ljungmani, O. gracilis, P. bifrons* and *E. affinis*, have highly synchronous reproductive cycles. We must infer that some exogenous factor(s) control synchrony of spawning and act as the ultimate selective factor determining reproductive seasonality[27].

Recent discoveries of seasonal periodicities in the physical environment and in sedimentary organic flux from the surface within the deep sea[4–6] suggest environmental factors have a role in the control of reproductive seasonality in deep-sea populations. The reproductive cycle of benthic invertebrates must be controlled at several levels: (1) initiation, (2) gamete development, (3) spawning, and (4) the period of larval development. Factors controlling both initiation of gametogenesis and gamete development are difficult to define[28] even in shallow-water species, although energy available as food will be a significant controlling factor for vitellogenesis. In shallow water, spawning is known to be precipitated by changes in the physical environment such as seasonal temperature fluctuations. Although such changes have been considered imperceptible in the deep sea, recent long-term measurements of current velocity show oscillations of varying period from semidiurnal and diurnal tidal components to low frequency signals, with seasonal maxima in late winter and minima in summer, in surface-generated kinetic energy[6,29]. Although rapidly diminished with depth, the seasonal effects of such kinetic energy (that in the Rockall Trough perhaps are associated with travelling disturbances created by mixing of Atlantic and Norwegian Sea water[29]) may be transmitted to abyssal depths well exceeding that of the 2,900 m deep Permanent Station[6]. Time-lapse photographs have shown that the behaviour of deep-sea fish may be influenced by semidiurnal tidal currents in the Bay of Biscay[30]. However, the possible role of low-frequency physical periodicities as proximate cues in triggering spawning of ripe echinoderms remains speculative. Possibly, secondary effects such as periodic sediment resuspension above critical erosive current velocities at the benthic boundary[31] are more important than direct effects of water motion on echinoderms lying on the seabed. However, chance, isolated triggering of spawning of an individual may be more rapidly transmitted throughout a ripe population by chemical signals in times of high water motion than in quieter periods.

Of considerably greater significance is the inference that in all the seasonally-reproducing deep-sea echinoderms, larvae are produced from February to June, coinciding with the springtime maximum in phytoplankton production in this area of the north-east Atlantic[32]. We believe that there is a sufficiently rapid transfer of small organic particles resulting from surface production, to the deeper water where, together with its associated bacteria, it would be available as food for the free-floating planktotrophic larvae. There is considerable evidence that this transfer of surface production to deep water is both rapid[33–35] and highly seasonal[4,5]. Such a cycle in the availability of surface-derived food material would be expected to influence the evolutionary selection for annual reproduction; larvae produced outside the period of elevated food supply being unlikely to survive.

Although we believe that this hypothesis is valid for deep-sea echinoderms with annual reproductive cycles, we have yet to determine whether such factors determine the reproductive strategies of other deep-sea invertebrates.

We thank the Master and crew of RRS *Challenger* for their help, Professor F. T. Banner for providing facilities and Mrs M. Pearson for help with the samples. The work was supported by NERC grant GR3/4131 to P.A.T., which is gratefully acknowledged, and a SERC research studentship to A.G. The Scottish Marine Biological Association is grant-aided by the Natural Environment Research Council.

Analysis of the dual role of phytochrome in the photoinhibition of seed germination

Michael R. Bartley & Barry Frankland

School of Biological Sciences, Queen Mary College,
University of London, London E1 4NS, UK

Light can both promote and inhibit germination, even of seeds of the same species[1–3]. Many seeds considered to be positively photoblastic are inhibited by prolonged irradiation with light of a wide variety of spectral qualities, including those, such as sunlight, that promote germination when given as a short exposure[4]. The promoting effect of light is mediated by the red/far-red reversible receptor pigment phytochrome operating in its P_{fr} form. The nature of photoinhibition is much less clear, although it is possible that continuous excitation of phytochrome is involved[5]. It has been suggested that light could control photomorphogenesis in seedlings not only through the establishment of a particular amount of phytochrome in its active P_{fr} form but also by determining the rate of 'cycling' between P_r and P_{fr} forms[6,7]. Such effects of prolonged irradiation are both wavelength and fluence rate dependent. We show here that the photocontrol of seed germination in *Sinapis arvensis* L. involves a promoting reaction dependent on the proportion of phytochrome in the P_{fr} form at photoquilibrium (ϕ) and an inhibiting reaction dependent on the rate of phytochrome interconversion or 'cycling' (H). Thus percentage germination can be quantitatively predicted from the spectral quality and the fluence rate of the seed's light environment.

The photoinhibition of seed germination under prolonged light does not show reciprocity (dependence on the product of fluence rate and exposure time), the length of the irradiation period being an important factor independently of total fluence. The action peak of the response occurs at about 710–720 nm in the few species studied, such as *Lactuca sativa* L.[7,8] and *Poa pratensis* L.[9]. This is characteristic of the 'high irradiance reaction', most studied in seedling photomorphogenesis[7,10,11]. However, in seed germination the high irradiance reaction is antagonistic to the low energy inductive reaction, whereas in seedling photomorphogenesis the two processes are synergistic.

The light reactions of phytochrome can be summarized in the following way:

$$P_r \underset{k_2\,(=N\sigma_2)}{\overset{k_1\,(=N\sigma_1)}{\rightleftarrows}} P_{fr}$$

where N is the photon fluence rate, and σ_1 and σ_2 are the photoconversion cross-sections. Light establishes a photoequilibrium between P_r and P_{fr}, expressed as the proportion of total phytochrome (P) in the form P_{fr}, ϕ. If a constant amount of phytochrome is assumed (there is very little evidence for P_r synthesis or P_{fr} destruction in seeds, although it is difficult to make direct measurements on phytochrome in the tissue of small seeds), then ϕ will be proportional to the amount of P_{fr} provided that the thermal reversion of P_{fr} to P_r is slow relative to the light reactions. However, this represents a dynamic condition of pigment interconversion, both reactions occurring simultaneously although with different rate constants. Thus for any given light condition there is a characteristic 'cycling rate' or 'photostationary flux'. The 'relative' cycling rate is here designated as H. Both ϕ and H can be calculated from the spectral photon distributions of the light source, using published[12] values of the phytochrome photoconversion cross-sections (σ_1 and σ_2) and the following equations:

$$\phi = \frac{\Sigma N_\lambda \sigma_{1\lambda}}{\Sigma N_\lambda \sigma_{1\lambda} + \Sigma N_\lambda \sigma_{2\lambda}}$$

$$H = (1-\phi)\Sigma N_\lambda \sigma_{1\lambda} = \phi\, \Sigma N_\lambda \sigma_{2\lambda}$$

It is also possible to estimate ϕ and H for a particular light source by spectrophotometric measurements on dark grown seedling tissue, which is rich in phytochrome. Tissue is exposed to the light source for increasing periods of irradiation, and the

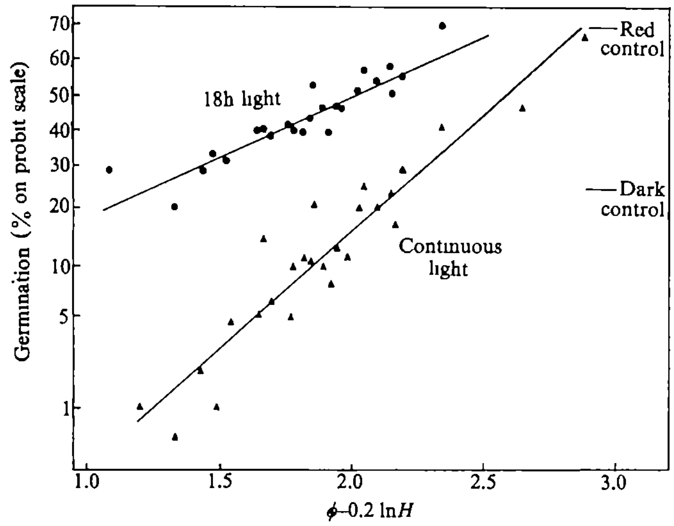

Fig. 2 Germination of *Sinapis* seeds in light of varying ϕ and H at 15 °C. Seven values of ϕ were used ranging from 0.05 to 0.70. Each point represents the mean percentage germination of four dishes of 50 seeds each. Standard errors were in the range 1 to 4, the average being 2. These were placed in a crossed gradient consisting of five 1.5 m 65/80W cool white (daylight) fluorescent tubes (with half their length blacked out) at one end (establishing a high ϕ value), and a 1-kW incandescent spotlight at the other end. The spotlight was placed behind a filter consisting of 10 cm of water, and one layer of no. 5A deep orange and one of no. 20 deep blue primary Cinemoid, which removed practically all irradiation below 700 nm and thus established a low ϕ value. Seeds were exposed either continuously from the start of imbibition until final germination was reached (▲), or as part of the following regime: 24 h dark – 5 min red – 5 h dark – 15 min far-red – 18 h treatment – 15 min far-red – 3 d dark (●). ϕ and H were determined by spectral measurement using a modified ISCO model SR spectroradiometer with a cosine-corrected remote probe. Spectrophotometric measurements of the P_{fr}/P ratio were made on dark-grown *Avena* coleoptiles which were kept on ice throughout exposure to the light. The coleoptiles were then packed into a specially designed cuvette under green safelight, and transferred to a Hitachi/Perkin-Elmer 156 digital dual wavelength spectrophotometer with a special actinic irradiation accessory.

proportion of phytochrome as P_{fr} measured in each case. ϕ is the P_{fr}/P ratio after a saturating irradiation. H can be calculated from ϕ and the time ($t_{\frac{1}{2}}$) to reach the half-saturation value of P_{fr}/P. For the reaction $P_r \rightarrow P_{fr}$:

$$k_1 = N\sigma_1 = \frac{\ln 2}{t_{\frac{1}{2}}}\phi$$

$$H = (1-\phi)k_1$$

$$= \frac{\ln 2(1-\phi)\phi}{t_{\frac{1}{2}}}$$

In this study ϕ and H were varied by setting up a crossed gradient with two light sources at opposite ends of a constant temperature (15 ± 1 °C) growth room. There was a low ϕ value at one end of the room, and a high ϕ value at the other end. ϕ and H were determined at several positions along the gradient, both by spectral measurement and spectrophotometric measurement on coleoptile tips. The two independent methods of determining ϕ and H gave very similar values.

Thus ϕ and H can be used to describe the light environment in terms of the photoreactions of phytochrome. These values may not necessarily reflect the state of phytochrome within the seed, as this is affected by the transmission characteristics of the seed coat and internal tissues.

The photocontrol of *Sinapis* seed germination at 15 °C is summarized in Fig. 1. This shows the normal red/far-red reversible germination response, with a short far-red treatment inhibiting germination below the dark level. An 18-h period of high fluence rate light which establishes a ϕ value of 0.27 will reduce germination below this far-red level. If a 5-h dark period is given between red and far-red pulses, the seeds escape far-red reversion. This indicates that P_{fr} action, whatever this may entail, has been completed. However, it is still possible to block the product of P_{fr} action by giving an 18-h period of high fluence rate light after the escape from reversion, and low fluence rate light has a blocking effect as well, although reduced. The data show that the photoinhibition process is both time and fluence rate dependent.

There appears to be two processes controlling *Sinapis* seed germination. P_{fr} is essential for an early event in the processes leading to germination. However, a time- and fluence-rate-dependent process will block germination at a stage after the apparent completion of P_{fr} action. These two processes can thus operate sequentially, which can lead to the loss of photoinduction so that the P_{fr} promoted process must be repeated. Thus in the natural light environment the two processes will operate simultaneously and antagonistically.

Seeds were sown in dishes along the crossed gradient to examine the relationship between germination and the two phytochrome parameters, ϕ and H. H was varied by shading the seed dishes with muslin or Cinemoid neutral density filters. The prolonged irradiation period was given both after the completion of P_{fr} action and continuously from the start of imbibition. It was found empirically that for a given ϕ value, the probit of germination was inversely proportional to the logarithm of H, and that the proportionality constant was ~0.2 for all ϕ values in both types of experiment. The straight line relationship between a mathematical expression combining ϕ and H and subsequent germination is illustrated in Fig. 2. This shows the antagonism between ϕ and H in the events leading to germination. From this relationship it is possible to predict the percentage germination of *Sinapis* seeds from a description of the light environment in terms of ϕ and H.

A theoretical 'action spectrum' can be generated from this relationship by choosing a particular level of response and calculating the value of H which will give this response for monochromatic irradiations across the spectrum. The absolute photon fluence rate required at each wavelength to achieve this response can be back-calculated from H. The reciprocals of these values when plotted against wavelength produce the action spectrum shown in Fig. 3. This should only deviate from an experimental action spectrum in those parts of the spectrum where the rate of P_{fr} dark reversion is appreciable compared with the rate of the photoreactions.

The striking point about this generated action spectrum is its similarity to experimental action spectra published for the high irradiance reaction in seeds[7,9]. It is therefore reasonable

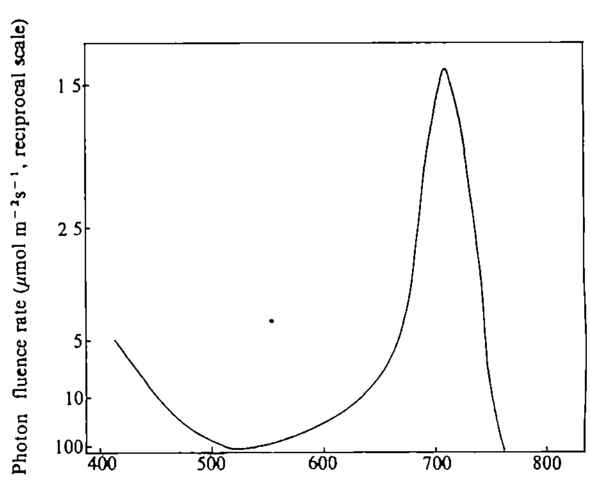

Fig. 3 Relationship between wavelength and calculated photon fluence rate giving half-maximum germination in *Sinapis* seeds. These were calculated using the expression $\phi - 0.2 \ln H = 1.93$, the latter being obtained from the data for 18-h irradiations given after escape from reversion.

to assume that these action spectra (strictly speaking these data for wavelength dependence are not true action spectra) arise because of the interaction of two aspects of phytochrome, the photoequilibrium ϕ and the photoconversion rate H. Further unpublished experiments using the seeds of *Plantago major* L. and *Bromus sterilis* L. support this view. Seeds of *Bromus sterilis* are apparently unique in that P_{fr} actually inhibits germination[13], and experiments using prolonged irradiations with this species suggest that P_{fr} and H will interact such that both processes inhibit germination.

Regeneration of normal and fertile plants that express octopine synthase, from tobacco crown galls after deletion of tumour-controlling functions

Henri De Greve*, Jan Leemans*, Jean-Pierre Hernalsteens*, Lin Thia-Toong*, Marc De Beuckeleer†, Lothar Willmitzer‡, Leon Otten ‡, Marc Van Montagu*† & Jeff Schell*†‡

Crown gall, a neoplasmic transformation of plant cells, is caused by transfer and integration into nuclear plant DNA of T-DNA, a segment of the Ti plasmid of *Agrobacterium tumefaciens*[1–8]. In plant cells, this T-DNA is expressed[9–12] and determines the morphogenetic growth properties of crown gall cells[12–16] and the synthesis of opines[17–21]. The T-DNA in octopine crown galls is composed of either one or two fragments derived from a continuous Ti sequence. Thus far, all octopine tumour lines contain the TL fragment (14 kilobases (kb)), whereas TR-DNA (~6 kb) can be present as an additional sequence[22–24]. Foreign DNA, inserted in the T region of a Ti plasmid, is co-transferred to the plant genome[17,18,21]. However, an important requirement for the use of T-DNA as vectors for plant genetic engineering is the regeneration of normal plants which stably maintain, express and sexually transmit the transferred DNA. We report here the isolation, from tumour tissues induced by mutant Ti plasmids, of morphologically normal plants that produce octopine synthase in all tissues. This enzymatic activity is inherited as a dominant mendelian marker[25]. These regenerated plants retained and expressed only the octopine synthase gene of the T-DNA.

On *Nicotiana tabacum*, *Agrobacterium* strains harbouring the mutant Ti plasmids, pGV2100 (ref. 15) and pGV2206 (ref. 21), induced small, greenish tumours covered with numerous shoots, whereas infection with the wild-type octopine plasmid resulted in large, white tumours without visible differentiation. Bacterium-free tumour tissue cultures induced by these mutant Ti plasmids proliferate on hormone-free medium at the same rate as wild-type tumour cells and they synthesize octopine. The greenish aspect and the ability to form shoots were maintained after repeated subculturing.

In an initial experiment 250 shoots from 9 independent tumour lines induced by pGV2100 were tested, and one was found to synthesize octopine. This plant, rGV1 (ref. 25), was derived from tumour line lGV20 and developed normal roots on culture on hormone-free Murashige and Skoog[26] medium.

Out of 250 shoots, from 8 independent pGV2206 tumour lines incited on tobacco and growing at 25 °C, no octopine-positive shoots could be recovered. Teratomata formation by tumours induced by nopaline strains on tobacco was increased by incubation at 33 °C. Under these circumstances both normal shoots, able to form roots after separation from the tumour, and teratoma-like shoots unable to form roots were observed for the pGV2206-induced tumour lines. From these tumour lines 250 shoots were derived at 33 °C and analysed for the presence of octopine. One tumour line, lGV23, produced 4 octopine-positive plants in 54 shoots tested. Like rGV1, these regenerates, rGV2, rGV3, rGV4 and rGV5, were morphologically normal and could be transferred to soil. Physical analysis of the regenerates by Southern blotting hybridization revealed that they were identical (G. Gheysen, personal communication).

The octopine-positive regenerates obviously differ from suppressed nopaline teratoma shoots obtained from T37 nopaline tumour lines[27–30] in the following aspects. (1) The shoots readily form a normal root system. (2) The shoots develop into plants which do not form spontaneous tumours and their cells are strictly dependent on exogenous hormones for division. (3) The regenerated plants respond to infection with agrobacterial strains carrying either wild-type or mutant Ti plasmids in an identical way to wild-type tobacco. (4) Earlier data, obtained with rGV1, showed that flower morphology and fertility were normal and that opine synthesis is completely retained through the meiotic process[25].

To determine whether all cells of the rGV4 express the octopine synthase gene, protoplasts were prepared from leaf mesophyll cells[25]. Fifty independent calli were tested and found to be positive for octopine synthase activity[31]. To test whether the T-DNA inserts were at identical or different chromosomal loci in rGV1 and rGV4, these plants were crossed and the offspring was analysed. Using a semiquantitative LpDH assay[23] a number of offspring plants were identified presumably containing both T-DNA inserts. Two of these plants were castrated and fertilized with pollen from wild-type W38-tobacco. In one case 71% of the plantlets and in the other case 76% were found to be octopine-positive. These results indicate that the T-DNA inserts in rGV1 and rGV4 are genetically unlinked.

The T-DNA-derived transcripts in the regenerated plants and in the parental tumour tissues were compared with those present in the wild-type octopine tumour line A6-S1 (Fig. 1). The pGV2100-induced tumour line lGV20 clearly lacks transcript 2, and contains a very reduced level of transcript 1 (Fig. 1). The pGV2206-induced tumours lack both transcripts 1 and 2 and contain normal levels of the other TL transcripts[16]. In contrast, rGV1 only expressed transcript 3, which specifies octopine synthase[20] (Fig. 1). Four lGV23-derived regenerates, rGV2, rGV3, rGV4 and rGV5, were also found to express transcript 3 only, as ^{32}P-labelled cDNA, made towards their poly(A)$^+$ RNA, hybridized solely with the T-DNA region overlapping with pTiB6S3 fragments *Sma*I-3b and *Eco*RI-7 (data not shown). Thus, the octopine synthase gene is the only TL-DNA gene that remained expressed in the octopine-positive plants.

We analysed the T-DNA sequences in lGV20 (tumour line) and in rGV1 (regenerated plant) by DNA/DNA hybridizations. These revealed that the T-DNA in lGV20 is co-linear with the T-region of pGV2100. In rGV1 DNA, however, only probes from the right end of the TL-DNA hybridized and revealed a single 3.2-kb fragment in a *Hin*dIII digest (Fig. 2). This indicated that secondary rearrangements have deleted most, if not

0028–0836/82/510752—04$01.00

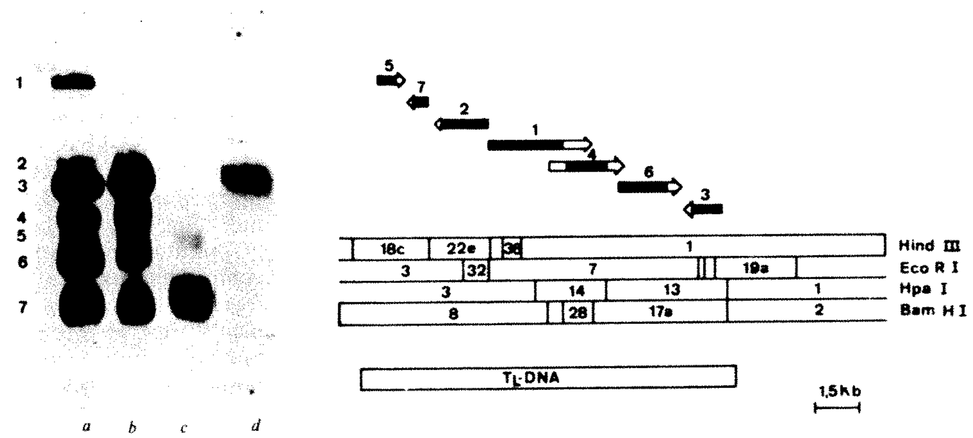

Fig. 1 Analysis of T-DNA transcripts. Total RNA isolation and selection of poly(A)$^+$ RNA fraction from leaves of rGV1, from callus of pGV2100-induced tumour line lGV20 and from the A6-S1 suspension culture was according to ref. 10. Electrophoresis in 1.2% agarose after denaturation with glyoxal/dimethyl sulphoxide, transfer to diazobenzyloxymethyl paper, pretreatment of the filters and hybridization to ^{32}P-labelled T-DNA probes were performed as described elsewhere[12]. Hybridization of poly(A)$^+$ RNA from wild-type octopine tumour line A6-S1 against total T-region probe (a mixture of nick-translated pTiB6S3 *Bam*HI fragment 8 and *Hin*dIII fragment 1) shows the seven TL-encoded transcripts (numbered 1 to 7 according to diminishing size) (lane *a*). Hybridization of poly(A)$^+$ RNA from lGV20 against total T-region probe (lane *b*) and against *Bam*HI fragment 8, which contains the complete coding sequences for transcripts 5, 7, 2 and part of the coding sequences for transcript 1 (lane *c*), clearly indicate the absence of transcript 2, a very reduced level for transcript 1 and wild-type levels of transcripts 5, 7, 4, 6 and 3. Hybridization of poly(A)$^+$ RNA from rGV1 against total T-region probe only lights up transcript 3 (lane *d*). The location of the seven TL-encoded transcripts on the physical map of the pTiAch5 T-region is from ref. 12. The direction of transcript 5 was determined from sequence data (J. Gielen, personal communication).

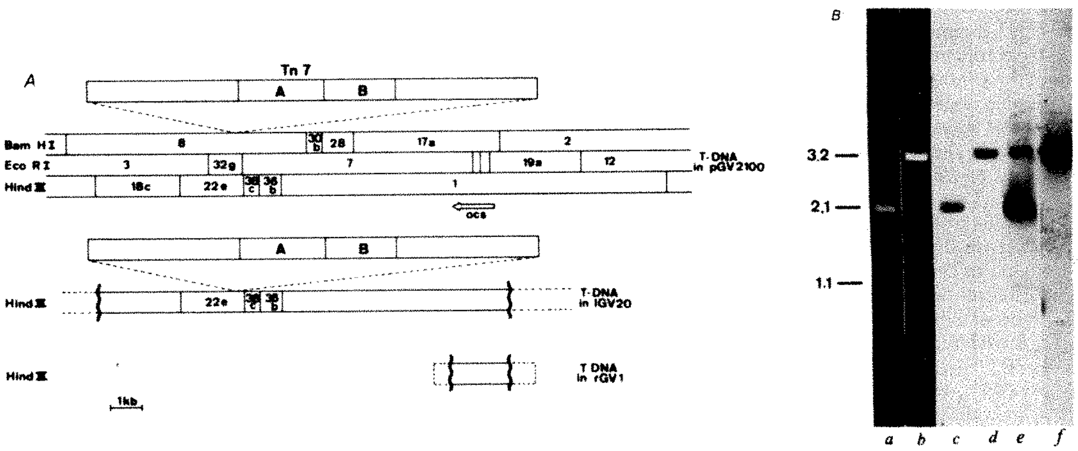

Fig. 2 Analysis of the T-DNA extent in lGV20 and in rGV1. *A*, Genomic blotting. DNA was prepared from lyophilized lGV20 tumour tissues and from rGV1 plants. Plant DNA (10 µg) was digested with *Hin*dIII and the fragments were separated by agarose gel electrophoresis, denaturated and transferred to nitrocellulose filters. Filters were hybridized against ^{32}P-labelled clones containing the right part (pGV0201)[34] and the left part (pGV0153)[34] of the pTiAch5 T-region and against pGV26[18], a ColE1 plasmid with a Tn*7* insertion. The interpretation of the resulting hybridization patterns is shown, the T-region in pGV2100 is shown for comparison. A and B are internal *Hin*dIII fragments of Tn*7* of, respectively, 2.7 and 2.25 kb[15]. The T-DNA in tumour line lGV20 is co-linear with the T-region of the inducing pGV2100. The T-DNA borders have the same approximate location as that described for most of the octopine TL-DNAs studied thus far[22–24]. No hybridization was observed using probes pGV0153 and pGV26 against rGV1-DNA. This indicated that most, if not all, of the left part of the T-DNA and the Tn*7* are absent in rGV1 DNA. Hybridization of *Hin*dIII-digested rGV1 DNA against pGV0201 revealed a single hybridization band of 3.2 kb. This band also lit up when the pTiAch5 *Bam*HI fragment 17 and *Hpa*I fragment 14, both internal T-DNA fragments situated at the right of the T-region, were used as probes. *B*, Genomic cloning. rGV1 DNA (50 µg) was digested to completion with *Hin*dIII and separated on a preparative low-gelling agarose gel. The DNA band corresponding to the 3.2-kb region was eluted from the gel[35]. Charon phage 21A was grown as described by Blattner in the detailed protocol that accompanies the Charon λ phages. Phage DNA was extracted from the purified phage as described previously[36]. The cohesive ends of the phage were annealed[36] and the phage DNA was digested with *Hin*dIII and treated with bacterial alkaline phosphatase to prevent *in vitro* packaging of the phage DNA without insert. 1 µg of insert DNA (±3.2 kb) was ligated with 10 µg Charon 21A phage DNA in 35 µl of ligase buffer[34]. Five packaging reactions, each containing 2.2 µg of recombinant DNA, were performed with *in vitro* packaging extracts prepared as described elsewhere[37]. *In vitro* packaged phages were preabsorbed to a fresh overnight BHB2600 bacterial culture[38] for 20 min at 37 °C[37], mixed with 0.7% top agar and plated at a density of 20,000 phage per 900-cm^2 plate. The plates were incubated at 37 °C for 14–16 h and refrigerated for at least 2 h before the nitrocellulose filters were applied. DNA was absorbed, denatured and bound to these filters as described previously[4]. Filters were prehybridized overnight at 42 °C in about 10 ml prehybridization mix (25 ml formamide, 2.5 ml 1 M HEPES *p*H 7.5, 2.5 ml 100 × Denhardt[39], 7.5 ml 20 × SSC[40], 1 ml 10 mg ml^{-1} yeast RNA, water to 50 ml). Denatured *Escherichia coli* DNA (50–100 µg ml^{-1}) was included in the prehybridization mix. The prehybridization and subsequent hybridization were carried out in a sealed plastic bag. The filters were hybridized with agitation at 42 °C for 24 h in prehybridization solution containing ^{32}P-labelled pGV0201 as probe. After hybridization, the filters were washed two or three times, each time with shaking, for 1 h at 50 °C in 500 ml washing solution (0.1 × SSC, 0.1% SDS), blotted dry and exposed to Fuji X-ray films with intensifying screens at −76 °C for 1–2 days. Plaques from the region of a plate corresponding to a positive signal on the autoradiogram were picked and resuspended in 0.5 ml λ phage buffer. The phage suspension was titrated and the plate containing ~100 plaques was rescreened. The process of picking positives and rescreening was repeated until ~90% of the plaques on a plate gave positive signals after screening. In this way, two independent, but identical clones were obtained. Phage DNA of these clones was prepared as described above and digested with *Hin*dIII. The 3.2-kb *Hin*dIII fragment was purified from low gelling agarose, digested with *Bam*HI and run in an agarose gel next to the *Hin*dIII fragment (lanes *a*, *b*). After transfer, the nitrocellulose filter was hybridized with purified *Bam*HI fragment 17a (lanes *c*, *d*) and subsequently with purified *Hin*dIII fragment 1 as probes (lanes *e*–*g*). The *Bam*HI fragment 17a only hybridized with the 2.1-kb fragment (lane *c*), whereas the *Hin*dIII fragment 1 hybridized with both the 2.1- and 1.1-kb fragments (lane *f*).

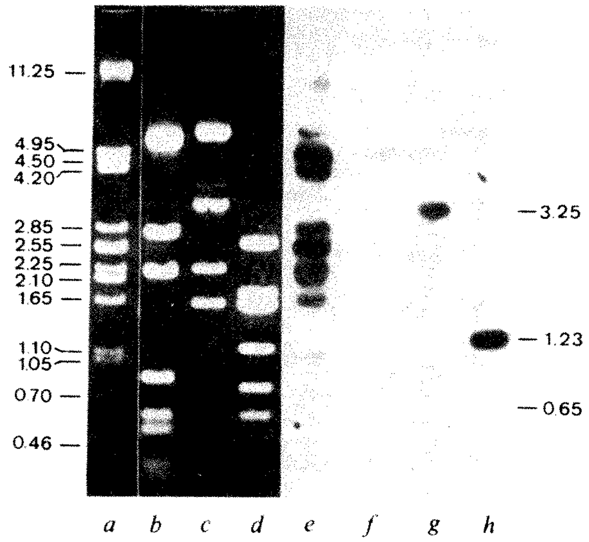

Fig. 3 T-DNA present in rGV1 mainly consists of sequences of the octopine synthase gene. Double digests, performed on different clones (lanes *b*–*d*) overlapping the whole TL-DNA, were blotted and hybridized with gcl rGV1-1 as a radioactive probe. No hybridization could be observed with the *Bam*HI–*Hin*dIII subfragments of *Bam*HI fragment 8 (lane *f*), and two out of three *Eco*RI–*Hpa*I subfragments of *Eco*RI fragment 7 (lane *g*). The two *Eco*RI–*Hpa*I subfragments which did not hybridize are the *Eco*RI–*Hpa*I fragment situated in *Bam*HI fragment 8 and the internal *Hpa*I fragment 14 of *Eco*RI fragment 7 (see Fig. 1). Hybridization of the genomic clone gcl rGV1-1 as probe against a *Bam*HI/*Sma*I double digest of *Bam*HI fragment 17a revealed that only the largest fragment hybridized (data not shown). To determine more precisely the end of the T-DNA in rGV1, a *Bam*HI/*Pvu*II double digest of *Bam*HI fragment 17a was hybridized with the genomic clone. Two of the four *Bam*HI–*Pvu*II subfragments lit up (lane *g*). This observation corresponds with the results obtained from sequence data which situated a *Pvu*II site in the 3′-untranslated region of the octopine synthase gene[32]. Lane *a*, λ digested with *Pst*I as molecular weight standard; lane *b*, *Bam*HI/*Hin*dIII double digest of clone pGV0153, containing the *Bam*HI fragment 8; lane *c*, *Eco*RI/*Hpa*I double digest of clone pGV0507[34], containing the *Eco*RI fragment 7; lane *d*, *Bam*HI/*Pvu*II double digest of clone pGV99[32], containing the *Bam*HI fragment 17a; lanes *e*, *f*, *g* and *h*, hybridization patterns obtained from, respectively, lanes *a*, *b*, *c* and *d*, using the genomic clone gcl rGV1-1 as probe.

all, of the left and middle of the T-DNA. A single hybridization band of 3.2 kb also appeared on hybridization of *Hin*dIII-digested DNA from rGV1 offspring obtained after selfing a flowering rGV1 plant, indicating that the T-DNA sequences of rGV1 passed through meiosis without rearrangements.

To confirm further and document the conclusion that the T-DNA in the rGV plants had sustained extensive deletions, genomic clones were prepared from rGV1 DNA using Charon phage 21A as vector. Two independent but identical clones were obtained (gcl rGV1-1 and gcl rGV1-2). A *Hin*dIII/*Bam*HI double digest of the gcl rGV1-1 clone gave two fragments of 2.1 and 1.1 kb, hybridizing to a probe containing the *Hin*dIII fragment 1 (Fig. 2*B*). The observed *Hin*dIII fragment of 3.2 kb presumably contained the *Bam*Hi site separating the T-region *Bam*HI fragments 17 and 2. Both the *Hin*dIII sites bordering this fragment must be derived from plant DNA sequences into which the T-DNA fragment is inserted. This conclusion was substantiated by demonstrating that (1) a probe containing *Bam*HI fragment 17a hybridized to the 2.1-kb but not to the 1.1-kb *Bam*HI–*Hin*dIII fragment (Fig. 2*B*); (2) clone gcl rGV1-1, when used as a probe against blotted TL-DNA fragments of pTiAch5, only hybridized with the right part of the TL-DNA (Fig. 3); (3) clone gcl rGV1-1, when used as a radioactive probe against a blotted *Eco*RI/*Bam*HI double digest of clone pGV105[32] (containing the *Eco*RI fragment 19a of the TL-DNA region of pTiAch5), hybridized with both the *Eco*RI–*Bam*HI fragments of the *Eco*RI fragment 19a (data not shown), indicating that the *Bam*HI site in the 3.2-kb *Hin*dIII genomic clone is indeed the site between *Bam*HI fragments 17a and 2; (4) the gcl rGV1-1 clone contains reiterated plant sequences bordering the remaining T-DNA sequences. Using either the 2.1-kb or the 1.1-kb *Hin*dIII–*Bam*HI subfragments as probes, in a Southern gel blotting hybridization against untransformed W38 tobacco DNA, a smear was obtained indicating that they both contained reiterated plant sequences.

This study proves that normal and fertile plants which still contain and express T-DNA sequences, can be regenerated from tobacco crown gall tumour cells. These 'transformed' plants are free of oncogenic properties and therefore fundamentally different from suppressed teratomata[27] or from opine-positive shoots lacking root formation and normal flower morphology[30]. The latter shoots needed to be grafted and developed into abnormal plants containing most, if not all, of the T-DNA sequences. The rGV plants described in this study, however, were shown to have lost all tumour-controlling genes by a secondary deletion in their T-DNA. The inactivation of most of the *onc* genes could therefore be essential for the regeneration of normal plants in tobacco[33].

Tumours in which TL-DNA transcripts 2, or 2 and 1, are absent seem to provide favourable conditions for the formation of shoots from nontumorous cells and from rare cells carrying a mutated T-DNA. Furthermore, our results do not distinguish whether the mutated T-DNA results from a secondary deletion after T-DNA integration, or from a mutant T-DNA present in only a few bacteria and transferred to a fraction of the transformed plant cells. If the latter were the case, we expect that Ti plasmids carrying a mutated T-DNA, similar to the one in rGV1, will efficiently transfer and integrate this T-DNA without inducing tumorous growth. The use of these mutated Ti plasmids as suitable vectors for gene transfer into dicotyledonous plants will then require: (1) appropriate conditions to regenerate plants from undifferentiated callus cultures; (2) a selective method to recover 'transformed' cells; indeed, it is likely that T-DNA-positive cells will be present only as a minority amongst wild-type cells.

It is important to stress that genes, such as opine synthases, introduced into plants via modified Ti plasmids, are stably maintained not only in somatic cells, but also through meiosis. Furthermore, independent insertions were shown to take place at different loci.

Finally, the finding that T-DNA-containing plants of the rGV1 type are fully susceptible to Ti plasmid-mediated transformation opens up the possibility of successive insertions of different genes in the same plant.

We thank Dr O. Schieder for the cloning, via leaf protoplasts, of somatic rGV4 cells, and Dr M. Holsters for advice and help with the cloning experiments in λ vectors. The mouse major transplantation antigens H-2K, H-2D and H-2L are highly polymorphic cell-surface glycoproteins which may serve as recognition elements in cell–cell interactions[1]. Each antigen possesses a number of alloantigenic determinants defined by antisera of various specificities. Recently, monoclonal antibodies have been produced which redefine and extend our knowledge of these determinants[2,3], but structural information has not yet been correlated with the serological definition of the antigens. We have previously reported the molecular cloning of genes for H-2L^{d} and H-2D^{d} transplantation antigens from the BALB/c mouse and the expression of these genes in mouse L cells[4,5]. To localize the serological determinants to discrete regions of the H-2 protein, we have now constructed new H-2 antigen genes by joining together fragments of the *H-2L*^{d} and *H-2D*^{d} genes. In L cells, these genes direct the synthesis of hybrid H-2 proteins and by using monoclonal antibodies of defined specificities, we have mapped classically defined serological specificities to structurally defined domains of the transplantation antigen protein. We conclude that polymorphic determinants recognized by monoclonal antibodies are located in functionally distinct portions of the protein.

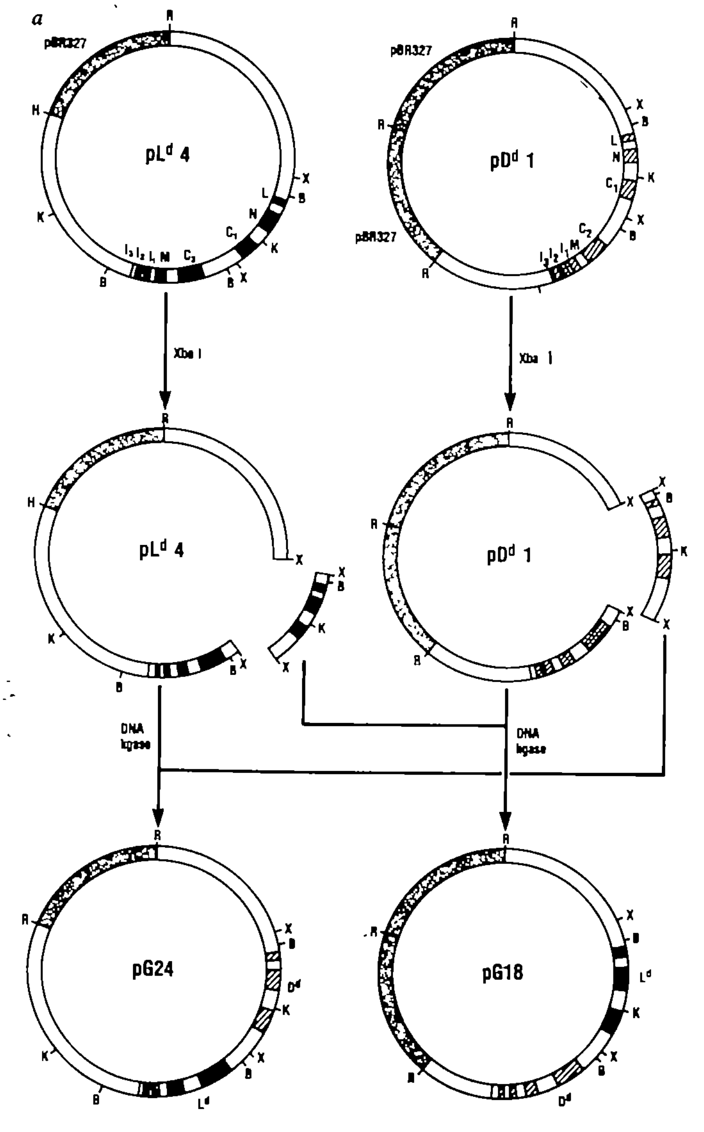
We obtained genomic clones containing *H-2L*^{d} and *H-2D*^{d} genes from a BALB/c mouse genomic library[4,5]. The DNA sequence of the entire 4.5-kilobase (kb) *H-2L*^{d} gene has been determined (refs 4, 6 and G.A.E., unpublished data). The three exons at the 5′ end of the *H-2D*^{d} gene have been sequenced and the derived amino acid sequence agrees precisely with the known H-2D^{d} protein sequence[5]. These genes were introduced into thymidine kinase(tk)-deficient mouse L cells by DNA-mediated gene transfer[7,8] and two cloned L cell lines were obtained which expressed H-2L^{d} and H-2D^{d} determinants in the presence of the parental *H-2*^{k} background. Thus, the H-2 phenotypes of these cell lines are H-2K^{k}, D^{k}, D^{d} (cell line T4.8.3) and H-2K^{k}, D^{k}, L^{d} (cell line T1.1.1). Using a panel of 13 monoclonal antibodies having H-2 specificities, we screened these cell lines for reactivity (Table 1). All three H-2L^{d}-specific monoclonal antibodies reacted with T1.1.1 cells but not with T4.8.3 cells. However, those antibodies reacting with antigens encoded by the *D* region of the *H-2*^{d} haplotype could not distinguish between determinants shared between H-2L^{d} and H-2D^{d} and those unique to H-2D^{d}, because of a lack of appropriate recombinant strains[9]. The availability of transformed cell lines separately expressing H-2D^{d} and H-2L^{d} antigens has allowed us to assess the precise specificities of the antibodies. Six monoclonal antibodies were found to be specific for the H-2D^{d}-producing cell line. The remaining three antibodies showed significant reactivity with both H-2L^{d} and H-2D^{d}, indicating specificity for a shared determinant (Table 1).

In order to more precisely define the structural basis of the allodeterminants recognized by these antibodies as well as allorecognition by T lymphocytes, we constructed hybrid *H-2* genes by combining exons from the cloned *H-2L*^{d} and *H-2D*^{d} genes. Several restriction endonuclease cleavage sites, including two *Xba*I sites, were conserved between the two sequences. After subcloning the respective genes into plasmid vectors, *Xba*I fragments containing the 5′ coding region of the genes were excised, exchanged and re-ligated with the 3′ end of the genes using T$_4$ DNA ligase (Fig. 1). This reconstruction resulted in two hybrid genes. The gene carried on the pG18 plasmid contains the three 5′ exons (L, N and C1) of *H-2L*^{d} and the 3′ exons of the *H-2D*^{d} gene. pG24 contains the first three exons of *H-2D*^{d} and the 3′ end of *H-2L*^{d} (Fig. 1*b*). If correctly expressed, the products of these genes would contain the N and C1 external domains of one transplantation antigen molecule and the C2 domain of the other.

To determine whether these hybrid genes could be expressed in mouse fibroblasts, pG18 and pG24 DNA was introduced into L(tk^{-})cells by DNA-mediated gene transfer[4,5]. Cloned cell lines from the resultant transformants were screened with a panel of monoclonal antibodies specific for H-2D^{d} and H-2L^{d} determinants. IgG class monoclonal antibodies were tested for binding by radioimmunoassay (Table 1*a*). One of the anti-H-2L^{d} antibodies, 28.14.8, reacted specifically with pG24-containing cells (T37.2.1) but not with pG18-containing cells, indicating that the determinant recognized by this antibody depends on the presence of the C2 domain of the H-2L^{d} molecule for expression. Although conformational interactions of widely separated portions of the molecule could be responsible for unmasking the monoclonal antibody determinant, the most likely explanation is that the 28.14.8 antibody recognizes a determinant physically located on the C2 domain of the molecule. Similarly, the determinants recognized by antibodies 34.5.8, 28.8.6 and 34.1.2 map to the N or C1 domains of the H-2D^{d} protein, the specificity of antibody 34.2.12 maps to the C2 domain of H-2D^{d}, and the specificity of antibody 30.5.7 maps to the N or C1 domains of H-2L^{d}. IgM class monoclonal antibodies, screened by flow microfluorimetry (Table 1*b*) show that H-2D^{d} specificities 34.4.21 and 23.5.21 map to the N or C1 regions of H-2D^{d} and the 23.10.1 determinant maps to the N or C1 domains of the H-2L^{d} molecule (Table 1*b*). Monoclonal antibodies 34.4.20, 27.11.13 and 28.11.5, which show cross-reacting specificities, react in all cases with both hybrid gene products. However, significant quantitative differences in binding suggest that these determinants are not identical. For example, antibody 34.4.20 binds significantly better to H-2D^{d}

0028-0836/82/510755—03$01.00



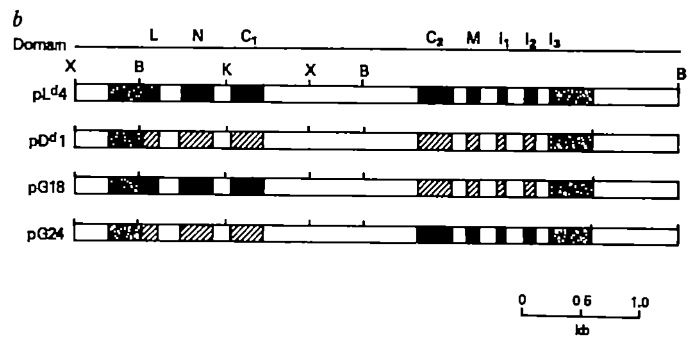


Fig. 1 Construction of recombinant genes from the cloned *H-2D*^{d} and *H-2L*^{d} genes. *a*, Fragments of the bacteriophage DNA containing *H-2* genes were subcloned into plasmid vectors for gene manipulation experiments. A 12-kb *Eco*RI-*Hin*dIII fragment from Ch4AH-2L^d (ref. 4) was subcloned into the *Eco*RI and *Hin*dIII sites of pBR327 (ref. 19), producing the plasmid pL^{d}4. Similarly, a subclone containing the *H-2D*^{d} gene, pD^{d}1, was prepared by subcloning the 8-kb *Eco*RI fragment of Ch4AH-2D^d (ref. 5) into the *Eco*RI site of pBR327. (As an artefact of this cloning procedure, pD^{d}1 contains two copies of pBR327 joined at the *Eco*RI sites in the same orientation.) Recombinants between the *H-2L*^{d} and *H-2D*^{d} genes were constructed by cleaving both plasmids with *Xba*I. The resultant fragments were purified by electrophoresis on 1% low melting point agarose gels and elution at 65 °C, followed by purification on DE-23 columns. The 1.6-kb *Xba*I fragment from pL^{d}4 was inserted into the 15-kb *Xba*I fragment of pD^{d}1 using 1 unit of T_4 DNA ligase in 10 mM Tris-HCl *p*H 7.6, 1 mM dATP, 0.5 mM EDTA, 6 mM $MgCl_2$ and 50 mM NaCl for 6 h at 14 °C. The 15-kb fragment was treated with bacterial alkaline phosphatase before ligation to prevent recircularization. The ligated DNA was reintroduced into *E. coli* LE392 by $CaCl_2$-induced transfection[17]. Colonies were screened for the insert having the correct orientation by 'mini-DNA' preparations[18] and the resulting hybrid plasmid, pG18, extensively mapped by restriction endonuclease cleavage to confirm the reconstruction. Similarly, pG24 was constructed by ligating the 1.6-kb *Xba*I fragment from pD^{d}1 to the 15-kb fragment from pL^{d}4. *b*, The resulting hybrid genes were recombined at the *Xba*I site located within the 1.3-kb intervening sequence separating the exons coding for the C1 and C2 domains. The hybrid *H-2* gene carried on pG18 contains the first three exons, corresponding to the L, N and C1 domains, of *H-2L*^{d} and the following five exons of *H-2D*^{d}. The gene on pG24 contains the L, N and C1 coding regions of *H-2D*^{d} and the 3′ domains of *H-2L*^{d}. Cross-hatched areas represent the regions coding for *H-2L*^{d}; solid regions represent those coding for *H-2D*^{d} domains. Stippled areas represent pBR327 (*a*) or the 5′ and 3′ untranslated regions of the *H-2* mRNA (*b*). L, N, C1, C2, M, I1, I2 and I3 refer to the regions of the protein encoded by each exon labelled by analogy to the *H-2K*^{b} prototype structure[10]. X, *Xba*I; B, *Bam*HI; H, *Hin*dIII; K, *Kpn*I; R, *Eco*RI cleavage sites.

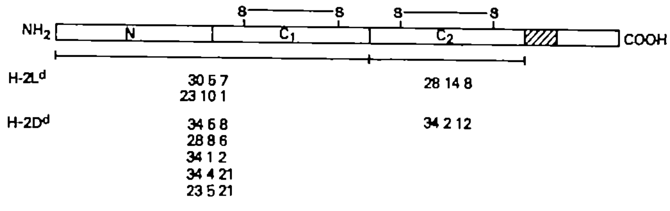

Fig. 2 Localization of polymorphic determinants on the external domains of H-2 proteins. This diagram summarizes the reactivity of H-2L^d- and H-2D^d-specific monoclonal antibodies with hybrid *H-2* genes. The reacting monoclonal antibody is listed in relation to the globular subunit of the protein to which it binds. The determinants recognized by monoclonal antibodies 30.5.7 and 28.14.8 have previously been shown to correlate with the classical serological specificities H-2.65 and H-2.64, respectively[2,12,13].

and the pG24 gene product (N and C1 of H-2D^d; C2 of H-2L^d) than to H-2L^d or the pG18 gene product. Monoclonal antibodies specific for N–C1 or C2 domains have been used to immunoprecipitate molecules from both T37.1.3 and T37.2.1 (G.A.E., unpublished). These immunoprecipitated proteins have molecular weights of 45,000 daltons and associate with β_2-microglobulin, consistent with the predicted hybrid protein structures.

This study demonstrates the feasibility of *in vitro* genetic recombination to generate hybrid, and thus allogeneically novel transplantation antigens which are expressed in a normal fashion on the cell surface. Thirteen determinants defined by monoclonal antibodies were active in the hybrid gene products. No determinants present in the two parental gene products were lost in either of the two hybrid gene products. Therefore the domain structure of the transplantation antigens may also define a functional separation of polymorphic antigenic sites. The location of antigenic determinants can be correlated with the domain structure of the molecule. Polymorphic determinants recognized by monoclonal antibodies are located on the N, C1 and C2 domains. Although the C2 domain shows significantly less variability in amino acid sequence than the N and C1 regions[10,11], polymorphic alloantigenic determinants may be located in this region of the protein also. Interestingly, monoclonal antibody 28.14.8 was originally found to be cross-reactive with the H-2D^b antigen. This study maps this determinant to the C2 domain and recent amino acid sequence data demonstrate that the C2 domains of H-2L^d and H-2D^b are identical[11]. In addition, monoclonal antibodies 28.14.8 and 30.5.7 correlate with serological specificities H-2.64 and H-2.65, respectively, originally defined by classical serology[2,12,13], which map to structurally distinct portions of the H-2L^d molecule (Fig. 2). Thus, the spatial relationships of polymorphic

Cloned *H–2* genes were introduced into thymidine kinase-deficient mouse L cells (DAP-3) by DNA-mediated gene transfer using the herpes virus thymidine kinase gene[16] as a selectable marker. The cloned cell lines T1.1.1, containing an *H–2L^d* gene[4] and T4.8.3, containing an *H–2D^d* gene[5], have been described elsewhere. These cloned cell lines have been maintained in continuous culture for over 6 months without loss or alteration of H–2 expression. Monoclonal antibodies specific for H–2D^d and/or H–2L^d determinants have been characterized previously[2,9]. *a*, IgG class monoclonal antibodies having specificities for H–2L^d or H–2D^d were screened for binding to transformed L cells containing *H–2L^d* *H–2D^d* or one of the two hybrid genes pG18 or pG24. Screening was performed by radioimmunoassay in Falcon flat-bottom 96-well microtitre plates. 10^6 cells were added to each well and incubated overnight at 37 °C in Dulbecco's modified Eagle's medium supplemented with glutamine, hypoxanthine, ammopterine, thymidine and 10% fetal calf serum[4]. After washing, 50 µl of a 1:1 dilution of hybridoma supernatant were added and the cells were incubated for 60 min at 4 °C. The cells were extensively washed, ^{125}I-labelled goat anti-mouse IgG added to each well, and the cells incubated for an additional 60 min at 4 °C. After extensive washing, cells were lysed with 1% Triton X-100, supernatants collected with a Titertek supernatant collection system, and radioactivity determined in a γ-spectrometer. Results are expressed as c.p.m. ^{125}I bound above background Each value represents the mean of triplicate samples with a standard deviation of less than 3% of the mean. Monoclonal antibody 28.8.6 was previously reported to react only with H–2K^b and H–2D^b (ref. 3) Additional cross-reactivities with H–2D^d have been found by radioimmunoassay and flow microfluorimetry (K.O , unpublished) *b*, IgM class monoclonal antibody binding was determined by flow microfluorimetry as described[4,5] using fluorescein-conjugated goat F(ab′)$_2$ anti-mouse F(ab′)$_2$. The results represent mean fluorescence normalized to gain 1 The fluorescent profile showed a single population of stained cells. Standard deviation of the mean fluorescence was less than 60 fluorescence units.

* Only the reactivity relevant to this study is shown.

determinants previously assessed only by competitive binding of monoclonal antibodies[2] may, using these techniques, be correlated with distinct molecular structures.

Monoclonal antibodies against H–2 specificities have been shown to specifically block cell-mediated lympholysis by T cells activated against H–2 allodeterminants[14,15]. Specifically, monoclonal antibody 28.14.8 has been shown to block both allogeneic and H–2-restricted cell-mediated lympholysis[14]. As shown here, the determinant recognized by antibody 28.14.8 is located on the C2 domain, a region which may, therefore, sterically affect H–2 antigen recognition by T lymphocytes. The use of H–2 antigens modified by genetic engineering coupled with *in vitro* mutagenesis makes feasible the complete structural and functional definition of allodeterminants on transplantation antigens and their recognition by T cells.

This work was supported in part by NIH grant GM19148. We thank David Stephany and Susan Sharrow for assistance with the FACS analysis.

Amplification of immunoglobulin λ constant genes in populations of wild mice

Cynthia L. Scott*†, J. Frederic Mushinski†, Konrad Huppi‡, Martin Weigert‡ & Michael Potter†

* Department of Zoology, University of Maryland, College Park, Maryland 20742, USA

The λ immunoglobulin light chain (Igλ) locus of BALB/c inbred mice consists of two variable region gene segments (V_λ)[1–3], and four constant region gene segments (C_λ)[1,2,4,5]. Each C_λ gene segment is associated with a unique joining segment (J_λ)[2,4–7], and they are organized in two paired units, J_3C_3–J_1C_1 and J_2C_2–J_4C_4 (refs 4, 8). Using cDNA probes specific for C_{λ_1} and C_{λ_2} (ref. 9) we have analysed the genomic organization of the C_λ gene segments in wild-derived and inbred strains of mice. Although Southern blots of the genomic DNA of inbred mice show a constant pattern of hybridization, wild-derived mice show a high degree of variation in the number, size and intensity of hybridizing fragments. We have now found that, per haploid genome, mice of a *Mus musculus musculus* stock isolated from Sladeckovce, Czechoslovakia (CzII) have at least 12 C_λ segments, and mice of a *Mus musculus domesticus* stock 'Centreville Lights' from Centreville, Maryland (CL) have at least 8 C_λ segments. There appears to have been relatively recent amplifications of the C_λ gene segments in wild mice.

The immunoglobulin C_λ J_3C_3–J_1C_1 and J_2C_2–J_4C_4 paired units share a similar internal organization[4,5,8] (Fig. 1). Considerable sequence homology exists between C_{λ_2} and C_{λ_3}; somewhat

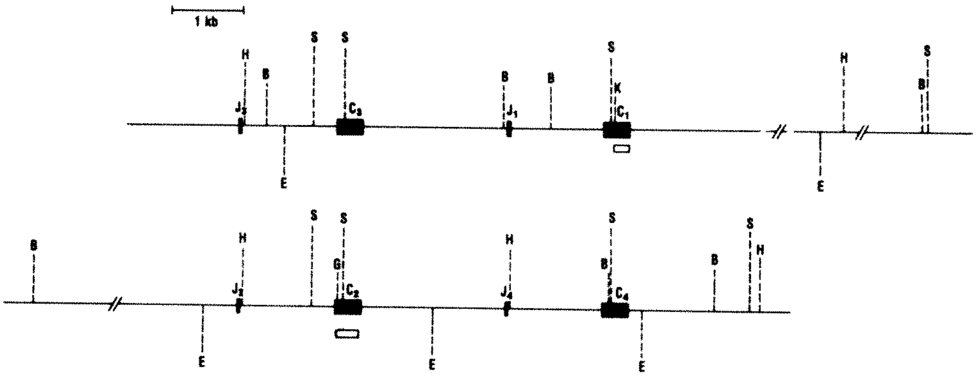

Fig. 1 Partial genomic map of inbred mouse C_λ locus constructed from data of Selsing *et al.*[8]. Black boxes denote coding sequences and open boxes beneath indicate regions included in cDNA hybridization probes. Restriction endonuclease sites are indicated and labelled thus: B, *Bam*HI; E, *Eco*RI; G, *Bgl*I; H, *Hin*dIII; K, *Kpn*I; S, *Sac*I. We prepared λ_1 cDNA from myeloma MOPC104E mRNA as described[10] with the following modifications: no actinomycin D was present in the cDNA synthesis reaction; whole DNA polymerase I was used in the second strand synthesis; *E. coli* strain MC1061[11] was transformed by the recombinant pBR322. Colony hybridization[12] using a cloned cDNA derived from the λ_1-secreting plasmacytoma, HOPCl (from S. Cory) was used to identify clones containing M104E λ_1 cDNA insert. A C_{λ_1}-specific cDNA fragment was generated by double-digestion of the MOPC104E λ_1 recombinant plasmid DNA with *Kpn*I and *Eco*RI, followed by purification by polyacrylamide gel electrophoresis[13]. A recombinant plasmid, pλII-1, containing M315 λ_2 cDNA was provided by A. L. M. Bothwell[9]. *Bgl*I digestion of pλII-1 and polyacrylamide gel purification generated a C_{λ_2}-specific cDNA fragment. The C_{λ_1}- and C_{λ_2}-specific cDNA fragments were identified on the basis of restriction enzyme mapping and comparison of results of hybridization to inbred mouse genomic DNA with those of Blombert *et al.*[4].

less homology is shared by C_{λ_1} and C_{λ_4} (ref. 8). Hybridization of C_{λ_1} cDNA to *Eco*RI digested inbred mouse liver genomic DNA identifies a 10 kilobase (kb) fragment containing the C_{λ_1} gene segment, and a fainter 2.8 kb fragment containing the C_{λ_4} gene segment (Fig. 2*a*, lane 1). There is no hybridization to C_{λ_2} or C_{λ_3} (ref. 4). Similarly, C_{λ_2} cDNA hybridizes to 10-kb and 3.2-kb fragments containing the C_{λ_3} and C_{λ_2} gene segments, respectively, but not to C_{λ_1} or C_{λ_4} (Fig. 2*b*). These *Eco*RI band patterns are representative of those observed for all inbred strains examined thus far: AKR/N, BALB/cAnπ, BALB/cJ, C57BL/Ka, C58, C3H/HeN, SJL/J, SJA, SWR/J, DBA/2, PL/J, BSVS, RF/J, 129/J, ST/bJ, SM/J, RIII, AuSSJ, CBA/ICR and CBA/T6T6. In striking contrast to the patterns observed with inbred strains are those obtained in many wild mouse populations, represented in Fig. 2 by two examples, CL (lane 2) and CzII (lane 3). The CL mouse *Eco*RI patterns contain six fragments that strongly hybridize to the C_{λ_1} probe and six that hybridize to the C_{λ_2} probe, while the same probes hybridize to eight and seven fragments, respectively, of CzII DNA digested with *Eco*RI.

Several explanations might account for the extra bands seen in CL and CzII DNA. Incomplete digestion by the endonuclease could give rise to more fragments hybridized to the cDNA probes. The same patterns for both inbred and wild-derived mice, however, have been seen repeatedly in stringently controlled digestion, blotting and hybridization conditions. Moreover, incomplete digestion of the DNA surrounding the C_{λ_3}–C_{λ_1} unit should give rise to fragments larger than the 10 kb fragments seen in inbred mice. Instead, all but one of the

Table 1 Number of fragments strongly hybridizing to C_{λ_1} and C_{λ_2} probes

Genomic DNA source	cDNA probe	*Eco*RI	*Bam*HI	*Hin*dIII	*Sac*I
BALB/c	C_{λ_1}	2	1*	2	3
(Inbred)	C_{λ_2}	2	2	2	1
M. musculus domesticus	C_{λ_1}	6	4	5	6
(Centreville)	C_{λ_2}	7	5	5	5
M. musculus musculus	C_{λ_1}	8	6	6	8
(Sladeckovce)	C_{λ_2}	7	9	6	6

Number of DNA fragments that strongly hybridize to C_{λ_1} and C_{λ_2} probes. The number of strongly hybridizing fragments generated under conditions as described previously is indicated. Highly intense bands, which may indicate the presence of multiple copies of a gene fragment, are counted as one band.

* Only one of the two *Bam*HI fragments hybridizes strongly. The C_{λ_4} gene fragment hybridizes very weakly and was therefore not counted.

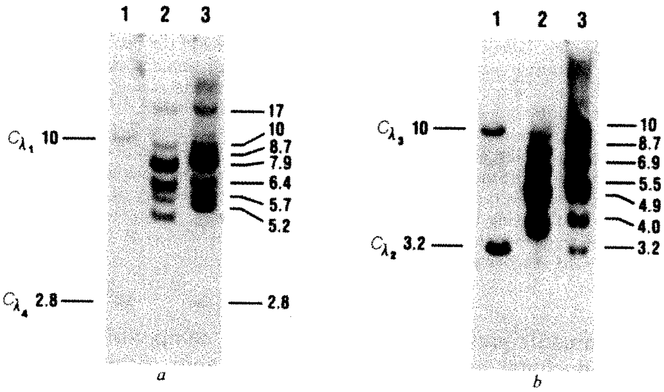

Fig. 2 *Eco*RI digested BALB/c, CL and CzII genomic DNA hybridized to C_{λ_1}- and C_{λ_2}-specific cDNA probes. Genomic DNA was prepared from mouse liver by homogenization in 5% citric acid, isolation of nuclei, lysis at 65 °C in 50 mM Tris-HCl *p*H 9.5, 100 mM EDTA, 1% SDS, sequential treatment with 500 $\mu g\ ml^{-1}$ pronase and 10 $\mu g\ ml^{-1}$ RNase, phenol extraction and ethanol preciptation. The data shown were generated by digestion of 10 µg of each DNA sample with restriction endonuclease (3–5 U per µg DNA) for 2–12 h at 37 °C, electrophoresis on 0.7% agarose followed by blotting onto nitrocellulose[14]. Before hybridization, blots were soaked in 6 × SSC (1 × SSC = 0.15 M NaCl, 0.015 M Na citrate), 10 × Denhardt's solution[15], 0.1% SDS and 60 $\mu g\ ml^{-1}$ sheared salmon sperm DNA for 2–4 h at 65 °C. 1×10^7 c.p.m. of C_{λ_1} or C_{λ_2} cDNA labelled by nick-translation[16] with [α-^{32}P]dCTP to $\sim 2 \times 10^8$ c.p.m. per µg DNA was hybridized to the genomic DNA blot overnight at 65 °C, in the same conditions as for prehybridization. The hybridized blots were washed once in 10 × Denhardt's solution, 2 × SSC, 0.1% SDS, 1 mM EDTA for 30 min at 65 °C, twice in 2 × SSC, 0.1% SDS, 1 mM EDTA for 30 min at 65 °C and twice in 0.2 × SSC, 0.1% SDS, 1 mM EDTA for 30 min at 65 °C. *a*, BALB/c (1), CL (2) and CzII (3) liver DNA hybridized to C_{λ_1} cDNA. *b*, Hybridization of the same DNAs to C_{λ_2} cDNA. The sizes (kb) of the BALB/c and CzII bands are indicated. Sizes were determined by comparison of the mobility of the hybridized fragment to a standard curve generated from linear regression analysis of 35 gels where *Hin*dIII fragments of phage λ DNA were used as DNA size markers. BALB/c fragments containing C_{λ_1}, C_{λ_2}, C_{λ_3} and C_{λ_4} genes were identified by comparison to published photographs[4] and restriction enzyme maps[8]. To ascertain that the hybridizations were indeed to C_λ coding regions and not to sequences related to the 3′ untranslated region, the λ_1 cDNA probe was fractionated to generate a fragment that contained coding region only and no 3′ untranslated sequence. When this fragment was labelled and hybridized to *Eco*RI digested BALB/c, CL and CzII genomic DNA under conditions as described above, we observed the same number of C_λ bands as seen in *a*, thus confirming hybridization to coding sequence.

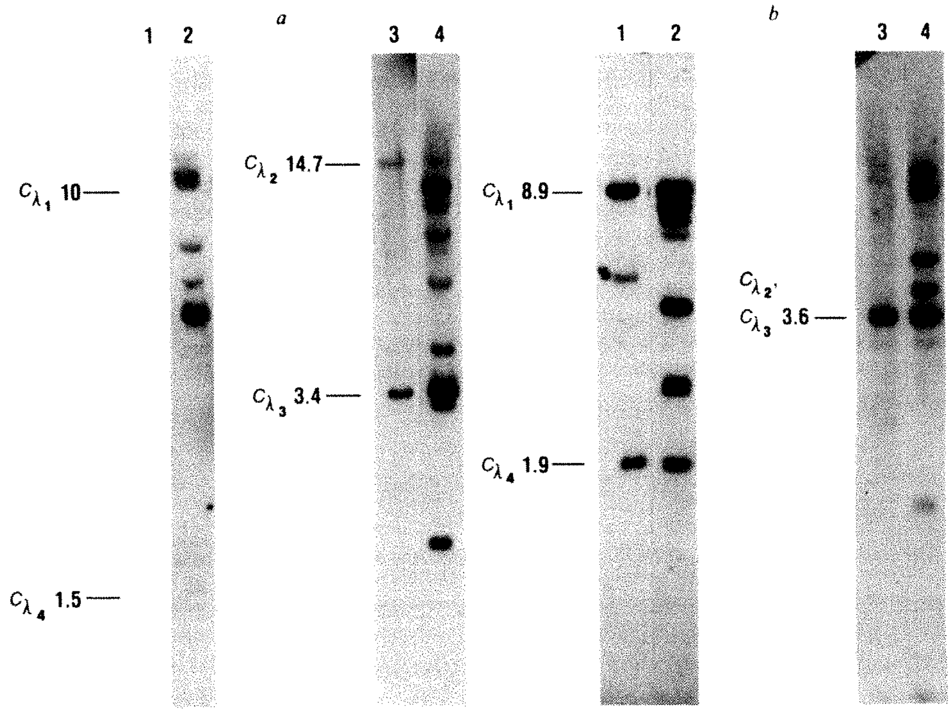

Fig. 3 Restriction endonuclease digestion (*a*, *Bam*HI and *b*, *Sac*I) of BALB/c (lanes 1, 3) and CzII (lanes 2, 4) DNA hybridized to C_{λ_1} cDNA (lanes 1, 2) and C_{λ_2} cDNA (lanes 3, 4). Digestion, hybridization and wash conditions were as described in Fig. 2 legend. Sizes of inbred mouse DNA fragments are indicated.

additional bands are smaller than 10 kb. Similarly, incomplete digestion products of the C_{λ_2}–C_{λ_4} unit would be larger than the 2.8 kb fragment of inbred mouse DNA hybridizing to the C_{λ_1} cDNA probe. Although the additional bands in CL and CzII are larger than 2.8 kb, the intensity of those bands is so much greater than that of the inbred mouse 2.8 kb fragment that it seems unlikely they are the result of incomplete digestion of that unit. As further evidence of completeness of digestion, when the same filters are stripped of labelled C_λ probe and rehybridized to probes independent of C_λ (for example, V_λ, C.L.S., manuscript in preparation), multiple bands are not present in CL and CzII DNA. Therefore, the patterns seen with the C_λ probes may be explained by the occurrence of multiple C_λ sequences in the DNA of CL and CzII.

Mutations generating *Eco*RI sites in the coding region of any of the inbred mouse C_λ gene segments would also give rise to additional fragments. However, the size range and number of the CL and CzII fragments is inconsistent with such an interpretation. In the unlikely event that multiple *Eco*RI sites have arisen in the coding region, which is only 318 base pairs (bp) in length, the fragments resulting from *Eco*RI digestion would, with the possible exception of those immediately adjacent to flanking regions, be very small and difficult to detect by Southern hybridization. A third basis for multiple bands in wild mice might be polymorphism and heterozygosity. Polymorphism does appear to exist between CL and other mice derived from the same population in Centreville, Maryland (C.L.S. and M.P., unpublished data). The difference between individuals, however, is not seen as multiple bands in one case and few in the other, but involves a difference of only one or two bands, depending on the restriction enzyme used. Heterozygosity may exist, because these colonies are maintained in an outcrossed fashion. However, all CzII individuals so far examined have the same pattern as do $(\text{BALB/c}\times\text{CzII})_{F_1}$ animals, which show BALB/c bands plus all CzII bands. Further, pooled genomic DNAs of mice derived from various localities in Eastern Europe and South-East Asia show a complex hybridization pattern similar to that of CzII. Even if polymorphism exists, it does not explain the large increase in number of C_λ bands seen in some of the wild populations. Instead, the patterns of C_λ fragments strongly suggest that more C_λ genes are present in these mice than in inbred strains.

To substantiate the multiple gene copy interpretation, we digested the same DNAs with *Bam*HI, *Hin*dIII, *Kpn*I and *Sac*I and hybridized with C_{λ_1} and C_{λ_2} probes. Multiple intense bands were visible in the wild mouse DNAs for all enzymes used, while inbred mice consistently had few bands (Table 1). Figure 3 shows examples of hybridizations to inbred (lanes 1, 3) and CzII (lanes 2, 4) DNA digested with *Bam*HI (Fig. 3*a*) and *Sac*I (Fig. 3*b*). The hybridization intensity of some of the wild mouse DNA fragments is substantially greater than that of the fragment containing the inbred mouse gene homologous to the cDNA probe. For example, the 7.9 kb *Eco*RI band of CzII is much darker than the 10 kb band of BALB/c, which contains the C_{λ_1} gene (Fig. 2*a*). Similar highly intense bands are visible in *Bam*HI digested CzII DNA hybridized to either the C_{λ_1} or the C_{λ_2} cDNA probe. The inbred mouse *Bam*HI fragments containing the C_{λ_1} and C_{λ_2} genes do not hybridize as strongly. This suggests that more than one copy of C_λ gene sequence is present in the strongest hybridizing fragments. On the basis of the intensity and number of additional fragments generated by digestion with five different restriction endonucleases, we conclude that CL and CzII mice have more C_λ genes than do inbred mice. In light of the fact that the inbred mouse C_{λ_1} and C_{λ_4} sequences do not cross-hybridize with the C_{λ_2} and C_{λ_3} sequences, it is apparent that the CL and CzII mice have multiplied sets of both C_{λ_1}-analogous and C_{λ_2}-analogous genes. Exact determination of the number of C_λ genes in the wild mice is not yet possible, but the independent C_{λ_1} and C_{λ_2} cDNA hybridization results indicate the presence of at least 8 in CL mice and 12 in CzII mice.

The four C_λ genes of inbred mice are presumed to be the product of duplication of a C_{λ_x}–C_{λ_y} unit[4,6,8], with C_{λ_x} as ancestor of C_{λ_2} and C_{λ_3}, and C_{λ_y} of C_{λ_1} and C_{λ_4}. Possible mechanisms of amplification include duplication of single C_{λ_x} or C_{λ_y} genes, sequential duplication of a C_{λ_x}–C_{λ_y} unit, or simultaneous duplication of multiples of the unit. When both the number and intensity of C_λ bands in CL and CzII are considered, the increase in number of C_{λ_x} and C_{λ_y} genes appears concordant, which more strongly supports a unit mechanism of duplication than the single gene duplication mechanism. Although it is not yet clear whether analogues to both inbred mouse C_λ units are involved, it seems that an analogue to the C_{λ_3}–C_{λ_1} unit has participated in the duplication process, as indicated by the intensity of bands hybridizing to C_{λ_1} cDNA. In duplication of a unit containing a C_{λ_y} gene that strongly hybridizes to the C_{λ_1} cDNA probe, there would be concordant duplication of a C_{λ_x} gene that strongly hybridizes to the C_{λ_2} cDNA probe. The hybridization patterns of CL and CzII are consistent with such a prediction.

The additional C_λ genes described in CL and CzII may be ancestral genes that segregated away from the progenitors of inbred strains, or they may represent a recent amplification of C_λ in some wild mouse populations. If the CL and CzII mice carry ancestral conserved genes, evolutionary drift of the DNA sequence would probably generate weaker hybridization bands than are observed. Thus, the strength of hybridization of inbred mouse C_{λ_1} and C_{λ_2} cDNA probes to CL and CzII C_λ genes seems to support recent amplification. There is evidence that duplication of C_λ genes has already occurred fairly recently in the mice from which inbred strains are derived, as indicated by the homology of the two C_λ units[4,6,8].

It is generally accepted that a single C_κ gene is adequate for expression of a large repertoire of immunoglobulin κ light chains in mice, so the role of multiple C_λ genes is not obvious. If J_λ amplification occurs concurrent with C_λ amplification, immunoglobulin λ diversity might ultimately be influenced. It may be that amplification of C_λ genes is associated with amplification of V_λ genes as well, but as the location of mouse V_λ genes relative to C_λ genes remains unknown, this possibility cannot yet be assessed.

We are currently preparing genomic clones from CzII mice to elucidate further the nature of the C_λ amplification at the DNA level. In addition, experiments at the RNA and protein levels are in progress to ascertain whether the additional C_λ genes are expressed.

We thank A. L. M. Bothwell, S. Cory, R. Riblet, J. Miller, E. Selsing, U. Storb and J. Owens for their help.

Inherited deletion of immunoglobulin heavy chain constant region genes in normal human individuals

Marie-Paule Lefranc[*], G. Lefranc[*,†] & T. H. Rabbitts

Laboratory of Molecular Biology, The MRC Centre, Hills Road, Cambridge CB2 2QH, UK

The existence of specific probes for human genes makes it feasible to study genetic abnormalities, both inherited and acquired, at the level of the genome. In this respect, the antibody genes of man are of particular interest as they represent a multigene family expressed in many leukaemias and immunodeficiency diseases. Furthermore, selective deficiency of immunoglobulins has been described in healthy individuals[1]. Normally, human adults express five types of immunoglobulin—IgM, IgD, IgG, IgE and IgA (defined by the class of heavy chain constant region). Subclasses are also known in IgG (IgG1, IgG2, IgG3 and IgG4) and IgA (IgA1 and IgA2) in which the immunoglobulins contain $\gamma 1$, $\gamma 2$, $\gamma 3$ or $\gamma 4$ and $\alpha 1$ or $\alpha 2$ C_H regions, respectively. Recently, a healthy Tunisian person was described who showed abnormal patterns of immunoglobulin expression[2]. The serum immunoglobulin of this individual, designated TAK3, was confined to IgM, IgD, IgG3, IgE and IgA2. We have now used cloned C_H-gene probes to study the DNA of TAK3 as well as two brothers, also Tunisian but apparently unrelated to the individual TAK3, and who show a similar immunoglobulin abnormality. We found that in these cases there seems to have been a large chromosomal deletion which includes three γ genes, an α gene and a pseudo-ε gene. This deletion accounts for the simultaneous absence of certain H-chain subclasses. These results illustrate that the human immunoglobulin gene locus is capable of undergoing rapid change, which is particularly apparent within small populations in which consanguinity is common.

The patterns of hybridization with C_H-gene probes of the DNA from TAK3, and the brothers TOU and EZZ were studied by Southern filter hybridization, and compared with DNA from individuals with normal immunoglobulin expression (both of Tunisian and European origins) plus a person, TAK14 (the daughter of TAK3), who is heterozygous for the immunoglobulin abnormality. The state of the γ genes in TAK3 and TOU was examined using a $\gamma 3$ probe (clone p3.6RH4.2, which contains a 3.6-kilobase (kb) *Eco*RI–*Hin*dIII fragment encompassing the whole $\gamma 3$ gene coding region[3]) and a $\gamma 4$ probe (clone pBRH4.1, which contains an analogous fragment encompassing the $\gamma 4$ gene[3]). These probes cross-hybridize with the genes for the various γ subclasses. A high degree of restriction fragment polymorphism has been observed in the γ genes; both the $\gamma 4$ probe (Fig. 1*a*) and the $\gamma 3$ probe (Fig. 1*b*) detect between five and seven hybridizing *Bam*HI fragments as exemplified by genomic DNAs from different individuals including a placental DNA obtained in Cambridge (Fig. 1*b*, lane 4) and two other Tunisian DNAs, designated LAT and BOU (Fig. 1*a*, lanes 1, 4). Common 9-, 11- and 12-kb fragments were present in all these DNAs, and in one DNA an additional 23-kb band was detected (Fig. 1*a*, lane 4) which we also observed in other Tunisian DNAs (data not shown).

When we analysed hybridization of the $\gamma 4$ probe with *Bam*HI-digested DNA from TAK3, we observed only two bands (8 and 10.5 kb; Fig. 1*a*, lane 3) whereas hybridization with the $\gamma 3$ probe showed only the 10.5-kb fragment (Fig. 1*b*, lane 2). Presumably, this 10.5-kb *Bam*HI fragment detected in TAK3 DNA represents the $\gamma 3$ gene (because only the IgG3 subclass is expressed in TAK3). The unusual size of this fragment may result from an altered restriction site which occurred during the deletion event. The origin of the second, more weakly hybridizing component could be the pseudo-γ gene[3,4] or even a partially deleted γ gene. Neither of the bands observed in TAK3 corresponds with the fragments detected in any of the other DNAs except TAK14 DNA (Fig. 1*a*, lane 2; *b*, lane 3) which is heterozygous for the immunoglobulin defect found in TAK3. The heterozygosity of TAK14 is demonstrated by the presence of a normal pattern of five bands plus the two unusual bands detected in TAK3 DNA. These data suggest that the simultaneous absence of $\gamma 1$, $\gamma 2$ and $\gamma 4$ subclasses in the homozygous individual TAK3 is due to an extensive deletion of the region of chromosome 14 which carries the γ genes[5–7]. The hybridization of the $\gamma 3$ probe to *Bam*HI-digested TOU DNA is also shown in Fig. 1*b* (lane 1). Interestingly, a similar γ deletion has occurred in TOU to that which occurred in TAK3, except that we could only detect the 10.5-kb hybridizing band in TOU DNA. These results with γ-gene probes show that two individuals displaying abnormal patterns of γ-globulin expression seem to do so because of inherited deletions of the respective γ genes.

A further investigation of the C_H-gene pattern in the TAK, TOU and EZZ DNAs was made using μ- and δ-specific probes (Fig. 2) plus ε- and α-specific probes (Fig. 3), and the latter two gave further evidence for gene deletions. The probes used

in Fig. 2 were C75pl.2 (a 1.2-kb *Eco*RI fragment of a human clone, carrying the C_μ coding regions, cloned into pACYC184[8]) and M13RP2 (a 1.5-kb *Eco*RI–*Pst*I fragment of a human clone containing part of the δ gene cloned into M13mp8). All five DNA samples analysed with the μ probe possessed 17-kb hybridizing *Bam*HI fragments (Fig. 2*a*) but in addition TAK14 and TAK3 showed a hybridizing band of 8 kb. The occurrence of this latter band in TAK3 (who is thought to be homozygous for the $\mathrm{C_H}$ locus[2]) is surprising; the most obvious conclusion must be that a duplication of μ has occurred in TAK DNA. No such putative duplication has occurred in the homozygous individuals EZZ or TOU, where we find only the 17-kb *Bam*HI restriction fragment (Fig. 2*a*, lane 5). A completely normal pattern of hybridization between TAK and TOU DNAs was found when we used the δ probe (Fig. 2*b*), as each of these DNAs display a 11-kb hybridizing *Bam*HI fragment found in 9 out of 10 control DNAs analysed (latter data not shown).

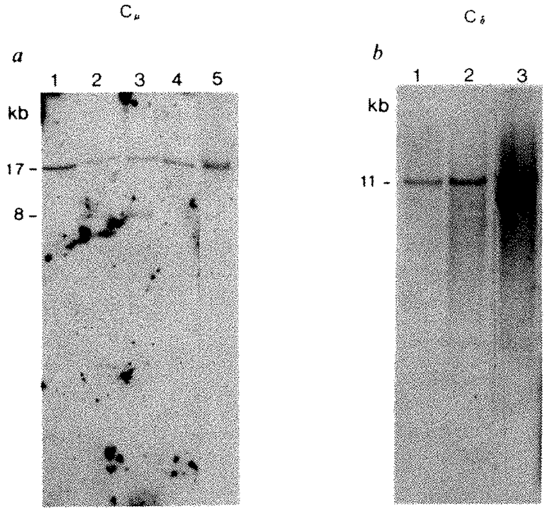

Fig. 2 Southern hybridization of Cμ and Cδ probes to genomic DNA from various sources. The DNA digests were: *a*, probe: μ; slot 1, LAT; slot 2, TAK14; slot 3, TAK3; slot 4, placenta; slot 5, EZZ. *b*, Probe: δ; slot 1, TAK3; slot 2, TAK14; slot 3, TOU. **Methods:** Genomic DNA was digested to completion with *Bam*HI, fractionated and blotted from 0.8% agarose gels onto cellulose nitrate and hybridized (as in Fig. 1) to nick-translated C75pl.2 (*a*) and M13RP2 (*b*) probes. Phage λ DNA cut with *Hin*dIII was used as molecular weight markers.

The ε and α genes in the various human DNAs were analysed using as hybridization probe for ε, the ε1.2BP25 clone (a 2.1-kb *Bam*HI–*Pst*I fragment, derived from the clone ε1.2, containing the entire human ε coding region[9]) and as an α probe the clone α2XP8 (a 600-base *Xho*I–*Pst*I fragment of an α-gene cloned in M13mp8[10]). The restriction pattern most frequently seen for ε-gene hybridization in human DNA (Fig. 3) is the presence of three *Bam*HI fragments (2.7, 6 and 9 kb)[9,11,12]. This pattern is exemplified in Fig. 3*a*, lane 3, by the DNA sample LAT. A frequently observed polymorphism is the presence of a fourth, 7.5-kb band[9], which is present in DNA sample BOU (Fig. 3*a*, lane 5). It has recently been demonstrated that the 2.7-kb fragment carries the active ε gene[9,11,12] whereas the 6- and 9-kb fragments represent pseudogenes called $\psi\varepsilon 1$ and $\psi\varepsilon 2$, respectively[10,11]. When we examined the patterns of hybridization of the ε probe to both TAK and TOU DNAs we again found evidence for gene deletion (Fig. 3*a*, lanes 1, 4). Both TAK3 and TOU DNAs show the presence of both the active ε gene and $\psi\varepsilon 2$ but no $\psi\varepsilon 1$. This observation is consistent with the deletion of the latter from these genomes because this gene is present in other DNAs (see, for example, LAT and BOU, lanes 3 and 5) including TAK14 who is heterozygous for the abnormality (Fig. 3*a*, lane 2).

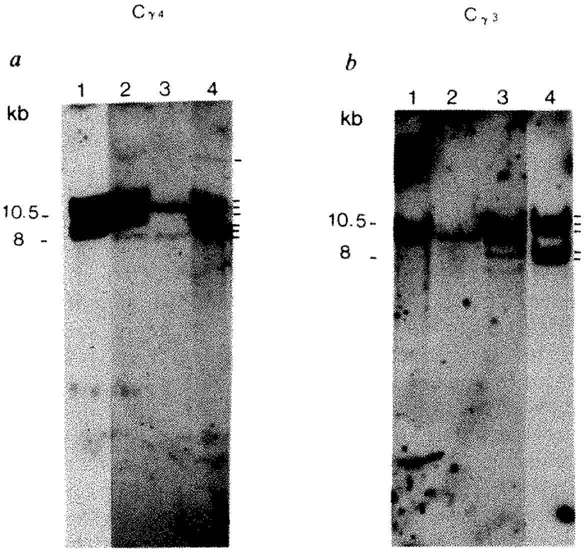

Fig. 1 Southern hybridization of Cγ3 and Cγ4 probes to DNAs from individuals showing serum immunoglobulin abnormalities. *a*, Probe: γ4; slot 1, LAT; slot 2, TAK14; slot 3, TAK3; slot 4, BOU. *b*, Probe: γ3; slot 1, TOU; slot 2, TAK3; slot 3, TAK14; slot 4, placental DNA.
Methods: DNA was digested to completion with *Bam*HI, the digests were fractionated on 0.8% agarose gel, and the DNA was transferred to cellulose nitrate filters[14]. LAT and BOU individuals were described previously[15]. The hybridization was carried out for 2 days at 65 °C using 6 × SSC, 0.1% SDS, 0.2% Ficoll 400, 0.2% bovine serum albumin (BSA), 0.2% polyvinylpyrrolidone (PVP) and 50 μg ml^{-1} sonicated, denatured, salmon sperm DNA[16,17], followed by washes in 1 × SSC, 0.1% SDS at 65 °C before autoradiography at −70 °C with prefogged X-ray film[18]. Probes were nick-translated to a specific activity of $\sim 10^8$ c.p.m. per μg. Size estimations (shown on the left of each panel) were made using λ cut with *Hin*dIII and the lines on the right of each panel signify location of restriction fragments discussed in the text.

The α-gene hybridization pattern observed using the α2XP8 clone with TAK and TOU is shown in Fig. 3*b*. In this experiment we used a sample designated TAK92 (a non-blood relative of TAK3) as the control DNA: hybridization of the α probe with TAK92 (Fig. 3*b*, lane 3) shows two hybridization components (2 and 1.2 kb) in common with European DNAs tested simultaneously (latter data not shown). Partial nucleotide sequencing data[10] indicate that the 2- and 1.2-kb fragments contain $\alpha 2$ and $\alpha 1$ coding sequences, respectively. The α-gene hybridization to DNA from TOU and TAK3 (Fig. 3*b*, lanes 1, 2) showed, in both cases, that the smaller of the hybridization components was absent, consistent with the presence of the $\alpha 2$ gene and deletion of the $\alpha 1$ gene from the genome of TAK3 and TOU individuals.

The Southern hybridization results presented here show that Tunisian individuals who exhibit simultaneous absence of IgG1, IgG2, IgG4 and IgA1 subclasses carry deletions for three γ genes (presumably $\gamma 1$, $\gamma 2$ and $\gamma 4$), a pseudo-ε gene ($\psi\varepsilon 1$) and an α gene presumed to be $\alpha 1$. These gene deletions account for the lack of specific immunoglobulin expression in these individuals. The precise location of the gene deletion in these people need not necessarily be identical but it does seem likely that switch or S-sequences are the key to the deletion event. The S-sequences are groups of short tandemly repeated units which are probably involved in the mechanism of the class switch and have been implicated in the formation of a mouse myeloma deletion mutant[13]. A likely hypothesis to explain the deletions described here is that illegitimate recombination has occurred within the germ line between non-adjacent S-sequences with resulting deletion of the intervening $\mathrm{C_H}$ genes. Presumably, such deletions occasionally occur in all human populations but would not normally be detected because they do not seem to be harmful (the person designated TAK3, for instance, is a healthy 75-yr-old woman). However, in populations where frequent consanguinity occurs the probability of

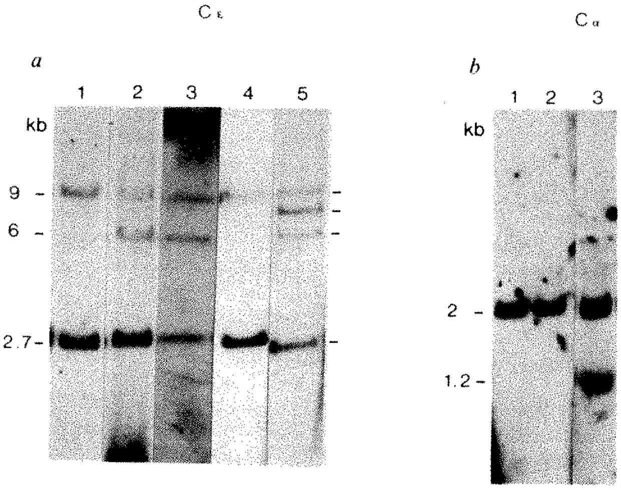

Fig. 3 Southern blot hybridization of Cε and Cα probes to genomic DNA digested with *Bam*HI (*a*) or *Pst*I (*b*). The DNA digests were: *a*, Probe: ε; slot 1, TAK3; slot 2, TAK14; slot 3, LAT; slot 4, TOU; slot 5, BOU. *b* Probe: α; slot 1, TOU; slot 2, TAK3; slot 3, TAK92.
Methods: Complete digests were separated on 0.8% agarose (*a*) or 1.4% agarose (*b*), blotted and hybridized (as in Fig. 1) with Cε probe (*a*) or Cα probe (*b*). The size of fragments (given on the left of each panel) were estimated relative to λ phage DNA cut with *Hin*dIII. The lines on the right of *a* mark the positions of fragments discussed in the text.

homozygosity.increases and such individuals are readily detected during random immunoglobulin haplotype screening.

Finally, the consistent deletion pattern of C_H genes in TAK, TOU and EZZ allows a link between the absence of C_H genes and the overall ordering of the human C_H genes described in the accompanying paper[10]. Two groups of cosmid clones have been described which seem to encompass $\gamma 3$-$\gamma 1$-$\psi\varepsilon 1$-$\alpha 1$ (region A) and $\gamma 2$-$\gamma 4$-ε-$\alpha 2$ (region B)[10]. As it seems that the deletions described here include $\gamma 1$, $\gamma 2$, $\gamma 4$, $\psi\varepsilon 1$ and $\alpha 1$ genes, the most probable order for the groups of cosmid clones is 5′ region A–region B 3′ as the deletions presumably start downstream of $\gamma 3$ (region A) and end upstream of the active ε gene (region B). We are now using gene cloning studies to clarify these issues as well as the nature and localization of the points of deletion within the C_H genes.

We thank the family members for continued interest and cooperation, also Erna van Loghem, Dr van der Meer, Dr van der Broek and Gerda de Lange for providing us with blood from TOU; H. Chaabini, A. N. Helal and J. Chibani for their collaboration; J. G. Flanagan for discussion; and A. Forster for technical help. This work was supported in part (G.L.) by INSERM grant CRL 801014.

Activation of the T24 bladder carcinoma transforming gene is linked to a single amino acid change

Elizabeth Taparowsky, Yolande Suard,
Ottavio Fasano, Kenji Shimizu,
Mitchell Goldfarb & Michael Wigler

Cold Spring Harbor Laboratories, Cold Spring Harbor,
New York 11724, USA

Several different transforming genes have been observed in the DNA of a variety of tumours and tumour cell lines of human and rodent origin by the ability of these genes to induce morphological transformation in NIH 3T3 cells[1–5]. The transforming gene found in a human bladder carcinoma cell line, T24, is H-*ras*-1, the human homologue of the Harvey sarcoma virus oncogene (v-H-*ras*)[6–9]. In the present study we have compared the H-*ras*-1 genes cloned from T24 and normal human DNA. The H-*ras*-1 gene cloned from T24 DNA induces transformation in NIH 3T3 cells, while the same gene cloned from normal cellular DNA does not. The functionally significant difference between the transforming and normal genes appears to be a single base mutation, which produces an amino acid change in the sequence of the proteins that the genes encode.

We had previously isolated transforming sequences from NIH 3T3 cells that had been transformed with DNA from T24 bladder carcinoma cells[10]. These sequences had undergone some rearrangement during gene transfer into NIH 3T3 cells. As a result of passage in NIH 3T3 cells, the transforming gene might have undergone less readily detectable secondary changes altering its biological activity. Therefore, in order to properly compare the transforming sequences of T24 to their normal counterparts, we directly cloned the H-*ras*-1 sequences from λ libraries constructed from T24 DNA and human placental DNA. From the T24 library we obtained seven independent isolates, all of which contained a 6.2-kilobase (kb) *Bam*HI H-*ras*-1 fragment with an identical restriction endonuclease pattern. From the placental library, we obtained clones of two types: in three (P3 type), H-*ras*-1 sequences were carried on a 6.7-kb *Bam*HI fragment: in the four others (P1 type), H-*ras*-1 sequences were carried on a 8.3-kb *Bam*HI fragment (see Fig. 1). Differences in the size of the *Bam*HI fragments were expected due to restriction endonuclease fragment length polymorphism about this gene in the human population[10].

We tested all of our isolates for the ability to induce foci of morphologically transformed NIH 3T3 cells on DNA mediated gene transfer. DNA from all T24 isolates of H-*ras*-1 efficiently transformed NIH 3T3 cells, while DNA from all placental isolates failed to induce foci. This difference must be the result of differences in DNA sequence. To facilitate our search for these differences, we tested the transforming activity of chimaeric genes. The restriction endonuclease *Xba*I cleaves the *Bam*HI fragment containing the H-*ras*-1 gene into one small and one large fragment (see Fig. 1). The large and small fragments were purified from each of the three cloned genes (types T24, P1 and P3), mixed and ligated in various combinations and finally cleaved with *Bam*HI. All (and only) molecules containing the small T24 *Bam*HI/*Xba*I fragment were capable of inducing transformed foci in NIH 3T3 cells (see Table 1). To further limit the area of our search we used restriction endonuclease *Mst*II, which cleaves the small *Bam*HI/*Xba*I fragment once. The 1.7-kb *Bam*HI/*Mst*II fragment and the 0.24-kb *Mst*II/*Xba*I fragment from the T24 or P3 H-*ras*-1 genes, and the large *Xba*I/*Bam*HI fragment from the P3 gene were purified, mixed and ligated in various combinations, and then cleaved with *Bam*HI. All molecules containing the 0.24-kb *Mst*II/*Xba*I fragment from T24 induced transformed foci in

0028–0836/82/510762—04$01.00

NIH 3T3 (see Table 1). The sequence changes in this region are therefore sufficient to confer the transforming capacity on the P3 H-*ras*-1 gene. A few foci are seen in one other combination of fragments (see Table 1) but we hesitate to ascribe significance to this.

We sequenced the 245-bp *Mst* ≤ I*Xba*I fragment in its entirety from P1, P3 and T24 H-*ras*-1 genes. The sequences were identical at all but two nucleotide positions (see Fig. 1). These lie within the first coding exon of the H-*ras*-1 gene as determined by a comparison of genomic sequences to those of an H-*ras*-1 cDNA clone. (O.F. *et al.*, manuscript in preparation).

We found that P1 and P3 H-*ras*-1 genes encoded glycine (GGC) at amino acid 12, while the T24 gene encodes valine (GTC) at that position, the result of a single G→T nucleotide change. We also noted that while all three genes encode histidine at amino acid 27, the codon usage differs (see Fig. 1). Because this latter change does not alter the protein sequence we believe it is not functionally significant (see below).

The above data suggest that an amino acid substitution in the T24 H-*ras*-1 gene product generates a protein with greatly enhanced transforming activity. To test this prediction, we have introduced the T24 and placental H-*ras*-1 genes into NIH 3T3 cells using the pSV2gpt vector of Mulligan and Berg[11]. In this way, we obtained 10 xgprt$^+$ lines containing the T24 H-*ras*-1 gene and 16 lines containing the P3 H-*ras*-1 gene, as determined by Southern filter blot hybridization (see Fig. 2). All ten of the lines containing the T24 H-*ras*-1 gene appeared morphologically transformed, while only two of the lines containing the P3 H-*ras*-1 gene had any of the features we associate with morphological transformation. To measure more precisely the degree of growth transformation we examined the ability of several lines to grow in agar suspension (see Fig. 2). To correlate degree of transformation with gene expression, we measured H-*ras*-1 RNA by filter hybridization and H-*ras*-1 protein by immunoprecipitation of ^{35}S-methionine labelled cell lysates (see Fig. 2). The human H-*ras*-1 gene encodes a 21,000-MW protein (p21) which cross-reacts with antibody to the Harvey v-*ras* p21 (given by M. Furth and E. Scolnick).

Table 1 Focus induction with chimaeric H-*ras*-1 genes

(5')*Bam*HI *Xba*I	*Xba*I *Bam*HI(3')		Foci per 0.1 µg*
T24	T24		358
T24	P1		142
T24	P3		80
P1	T24		0
P1	P1		0
P3	T24		0
P3	P3		0
(5')*Bam*HI/ *Mst*II†	*Mst*II/*Xba*I†	*Xba*I/ *Bam*HI(3')†	Foci per 0.02 µg‡
T24	T24	P3	88
T24	P3	P3	2
P3	T24	P3	163
P3	P3	P3	0

The T24, P1 and P3 *Bam*HI fragment containing the H-*ras*-1 gene was cleaved with *Xba*I and the respective 5' (*Bam*HI/*Xba*I) and 3' (*Xba*I/*Bam*HI) halves of the genes (see Fig. 1) purified from agarose gels as previously described[25]. The various 5' and 3' halves were mixed in equimolar ratios in the combinations indicated above, ligated with T4 DNA ligase at a DNA concentration of 100 µg ml^{-1}, and then digested with *Bam*HI. The amount of material in the correct molecular form was then estimated by ethidium bromide staining after electrophoresis in agarose gels.

* Approximately 0.1 µg of the chimaeric genes was mixed with 90 µg of NIH 3T3 carrier DNA and added to 3 plates of NIH 3T3 as a calcium phosphate precipitate as previously described[4]. Morphologically altered foci of NIH 3T3 cells were scored after 14 days.

† The 1.7-kb *Bam*HI/*Mst*II and the 0.24-kb *Mst*II/*Xba*I fragments were purified from the T24 and P3 *Bam*HI fragments (see Fig. 1), mixed in equimolar ratio with the 4.8-kb P3 *Xba*I/*Bam*HI fragment, ligated with T4 DNA ligase at a DNA concentration of 100 µg ml^{-1} and then cleaved with *Bam*HI. The amount of material in the correct molecular form was then estimated by ethidium bromide staining after gel electrophoresis.

‡ Approximately 20 ng of the chimaeric genes were mixed with 180 µg of NIH 3T3 carrier DNA and added to six plates of NIH 3T3. Foci were scored after 14 days.

In these studies, the only difference we can discern between the expression of the P3 and T24 H-*ras*-1 genes is the potency of their respective protein products. Highly transformed cell lines containing the T24 H-*ras*-1 gene (XT1 and XT3) contain far less *ras* p21 than do minimally transformed lines expressing the normal *ras* gene (XP1, XP3). We estimate from this that the T24-encoded *ras* p21 is at least 100 times more potent at inducing growth transformation than the P3-encoded *ras* p21.

We note that one line (XP2) containing the P3 H-*ras*-1 gene and expressing the highest levels of *ras* p21 does grow in agar to a significant extent. Thus it appears that normal H-*ras*-1 can mediate transformation if the gene product is overproduced. Other workers have reported that a normal allele of H-*ras*-1 acquires transforming activity when physically linked to a high efficiency retroviral promoter[12]. However, very high levels of the normal gene product are required to achieve the degree of

Fig. 1 Structural differences between human H-*ras*-1 genes. The *Bam*HI fragment containing the H-*ras*-1 gene was cloned from placental DNA and T24 DNA libraries constructed in the L47.1 cloning vector[13]. Phage libraries were constructed by the method of Hohn and Murray[14] and screened without prior amplification by the method of Benton and Davis[15]. Restriction maps of the three gene types (P1 and P3 from placenta, and T24 from T24 cells) are shown above. In the region of the 2.9-kb *Sst*I fragment (shaded area) which contains a complete H-*ras*-1 gene (unpublished data) the restriction maps are similar. The 245-bp *Mst*II/*Xba*I fragment, which contains the functionally significant structural differences, was sequenced by the method of Maxam and Gilbert[16] in entirety for all three genes. The sequencing strategy is shown in the middle panel. Restriction fragments were labelled at their 3' ends with the large fragment of DNA polymerase I[17]. All regions were sequenced at least once on both strands. The bold line indicates the first coding exon of 37 amino acids, determined by sequencing a T24 H-*ras*-1 cDNA clone (O.F. *et al.*, manuscript in preparation). In the bottom panel is shown the DNA sequence of T24 in this coding region and the predicted amino acid sequence. Where P1 and P3 differed from T24 are enclosed in boxes. Restriction endonucleases used were *Ava*I (A), *Bam*HI (B), *Bst*EII (Bs), *Mst*II (M), *Nar*I (N), *Pvu*II (Pv), *Sst*I (S) and *Xba*I (X).

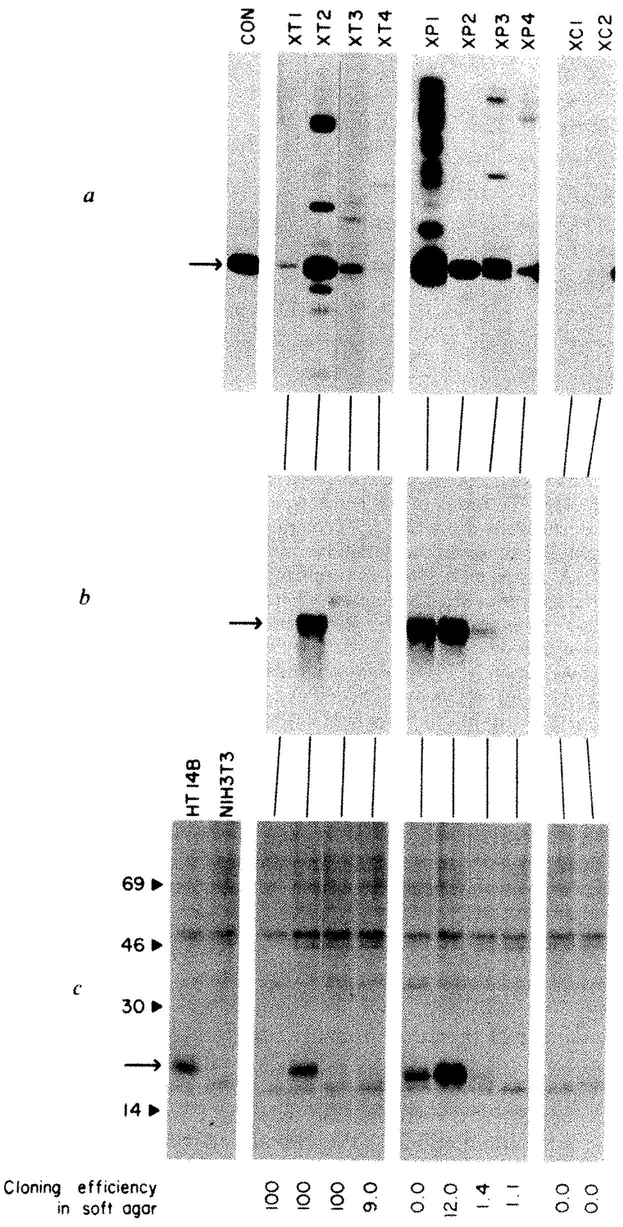

Fig. 2 Expression of normal and transforming H-*ras*-1 genes after co-transfer into NIH 3T3 cells. NIH 3T3 cells containing the human H-*ras*-1 gene cloned from T24 (XT1 . . . XT4) or from placental DNA (XP1 . . . XP4) were obtained by co-transfer[18] after selection for expression of the pSV2gpt vector[11] added in the presence of an excess of the purified *Bam*HI fragments containing the H-*ras*-1 gene. Cells were analysed for H-*ras*-1 gene sequences (*a*), expression of H-*ras*-1 transcripts (*b*), expression of the p21 *ras* gene product (*c*), and cloning efficiency in soft agar (bottom). XC1 and XC2 are NIH 3T3 cells containing the pSV2gpt vector but no human H-*ras*-1 gene. HT14B are NIH 3T3 cells transformed with unintegrated Harvey sarcoma viral DNA. *a*, 6 μg DNA from the indicated cell lines were cut with *Sst*I, electrophoresed in 1.0% agarose gels, filter•blotted according to Southern[19] and filters hybridized with 2.9-kb *Sst*I fragment purified from the human H-*ras*-1 gene (see Fig. 1) and nick translated with ^{32}P (ref. 20) to a specific activity of 3×10^8 cpm μg^{-1}. Filter hybridization and washing conditions were at 72 °C under stringent conditions as previously described[4]. Filters were autoradiographed at −70 °C for 15 h with XR5 film and intensifying screens. Lane labelled CON represents 100 ng of purified 2.9-kb *Sst*I fragment. The presence of the 2.9-kb *Sst*I fragment (arrow) indicates the presence of at least one functional copy of the H-*ras*-1 gene. Other hybridizing fragments represent integration events in which one or both of the *Sst*I sites flanking the H-*ras*-1 gene were destroyed. *b*, Cytoplasmic RNA from the indicated cell line was prepared[21] and 20 μg were electrophoresed in 1.0% agarose formaldehyde gels as previously described[10], filter blotted and hybridized according to Thomas[22] except that dextran sulphate was omitted. The hybridization probe was as described above. The arrow indicates the position of the 1.1–1.2-kb H-*ras* mRNA. *c*, Indicated cells were labelled for 6 h in methionine-free Dulbecco's medium containing 5% dialysed serum and 100 μCi ml^{-1}, 80 Ci mmol^{-1} ^{35}S-methionine. Washed cells were lysed in 1% Triton, 0.5% deoxycholate in phosphate-buffered saline containing 2 μg aprotinin (Sigma) and 1 mM phenylmethylsulphonylfluoride, and centrifuged at 100,000*g* for 12 h. Supernatants were preabsorbed with goat anti-rat IgG and *Staphylococcus aureus* protein A. Immunoprecipitation was performed for 5 h at 4 °C with anti-v-H-*ras* p21 monoclonal antibody, the generous gift of E. Scolnick and M. Furth. After addition of goat anti-rat IgG, immune complexes were absorbed to protein A. Pellets were boiled in SDS sample buffer[23] and analysed by SDS-polyacrylamide gel electrophoresis by the method of Blattler *et al.*[24]. Proteins were visualized after fluorography by exposure for 30 h to Kodak XR5 film. The arrow marks the position of migration of v-H-*ras* p21. Arrowheads are size markers ($\text{MW}\times 10^{-3}$) from ^{14}C-labelled standards (bovine serum albumin, ovalbumin, carbonic anhydrase and lysozyme; Amersham). Cloning efficiency in soft agar was determined by plating 10^5 cells in 5-cm dishes containing 0.35% Difco agar and Dulbecco's medium with 10% calf serum. 14 days later, numbers of colonies with greater than 10 cells were tabulated for each cell line by examination of six 2-mm diameter microscopic fields.

growth transformation mediated by low levels of an altered *ras* gene product.

We and others have shown transforming *ras* genes are present in many different human tumour cell lines[6-9]. We speculate that the activation of *ras* genes in these other cell lines is the consequence of somatic mutations in coding regions. If such mutations do occur in human tumour cells, the altered protein products might be immunogenic in their human hosts. The presence, therefore, of antibodies against *ras* proteins in humans may be diagnostic for certain forms of cancer.

We thank M. Furth and E. M. Scolnick for providing rat anti-P21 antiserum. K.S. is supported by the Robertson Research Fund. O.F. is on leave from I Istituto di Chimica Biologica, II Facoltá di Medicina, Università di Napoli, Italy. Y.S. is the recipient of a postdoctoral fellowship from the Schweizerische Stiftung fur Medizinisch-Bioloqische Stipendien.

Note added in proof: Substantially similar findings were recently reported for the transforming genes of T24 (ref. 26) and EJ (ref. 27), another bladder carcinoma cell line which we believe has arisen from T24 (M.W., M.G., J. Fogh, N. Dracopoli and M. Pollack, unpublished data). Most importantly, the predicted amino acid sequences are all in agreement. We note the following differences in the critical 245-bp *Mst*II/*Xba*I fragment: (1) a *Mst*II cleavage site 9 bases 5′ to the ATG start codon is predicted and present in the genes we have sequenced, but not predicted by the published sequences of the other groups. (2) A *Nar*I cleavage site 104 bases 3′ to the ATG start codon is predicted and present in the genes we have sequenced, but not found in the sequence published by Tabin *et al.*[27]. (3) An altered histidine codon is not observed for the normal gene sequenced by the other groups.

A cellular oncogene is translocated to the Philadelphia chromosome in chronic myelocytic leukaemia

The transforming genes of oncogenic retroviruses are homologous to a group of evolutionary conserved cellular *onc* genes[1]. The human cellular homologue (c-*abl*) of the transforming sequence of Abelson murine leukaemia virus (A-MuLV) was recently shown[2] to be located on chromosome 9. The long arm of this chromosome is involved in a specific translocation with chromosome 22, the Philadelphia translocation (Ph^1), t(9; 22) (q34, q11), which occurs in patients with chronic myelocytic leukaemia (CML)[3–5]. Here we investigate whether the c-*abl* gene is included in this translocation. Using c-*abl* and v-*abl* hybridization probes on blots of somatic cell hybrids, positive hybridization is found when the $22q^-$ (the Philadelphia chromosome), and not the $9q^+$ derivative of the translocation, is present in the cell hybrids. From this we conclude that in CML, c-*abl* sequences are translocated from chromosome 9 to chromosome $22q^-$. This finding is a direct demonstration of a reciprocal exchange between the two chromosomes[6] and suggests a role for the c-*abl* gene in the generation of CML.

The human c-*abl* sequences represent a cellular homologue of the transforming component of A-MuLV. This retrovirus is a recombinant between Moloney MuLV and mouse cellular c-*abl* sequences[7] and induces lymphoid tumours on *in vivo* inoculation of the mouse[8,9]. The major A-MuLV translational product has been identified as a poly-protein, $\mathrm{P120}^{gag\text{-}abl}$, consisting of amino-terminal structural proteins encoded by the M-MuLV *gag* gene, linked to an acquired cellular sequence encoded carboxy-terminal component[10,11]. This protein is one of several virus-encoded transforming proteins with tyrosine-specific protein kinase activity[12–15]. Similar oncogenic sequences of Harvey and Kirsten sarcoma virus are homologous to transforming sequences (c-Ha-*ras*, c-Ka-*ras*) isolated from human bladder and lung carcinoma cell lines[16–18]. Both these sequences induce transformation of mouse NIH 3T3 cells after transfection, establishing that the human genes have potential transforming activity. Recently, the human c-*abl* gene has been cloned in cosmids[19]. Using v-*abl* DNA as a probe, several clones containing overlapping sequences representing the entire c-*abl* gene were isolated from a human lung carcinoma cosmid library. The restriction enzyme map of the human v-*abl* cellular homologue, presented in Fig. 1, identifies areas of the gene which hybridize to v-*abl* sequences. The gene is distributed over a region of 40 kilobases (kb) of human DNA and contains multiple intervening sequences. On transfection of Rat-2 cells with the c-*abl* cosmids, no transforming activity was detected, not unexpectedly, as none of the cosmid clones tested contained the entire c-*abl* gene[19].

By Southern blot analysis of a series of somatic cell hybrids, the human c-*abl* gene has been localized on chromosome 9[2]. This finding is of interest because of the involvement of the long arm of chromosome 22 (band 22q11) in a specific translocation with the long arm of chromosome 9 (band 9q34), the Philadelphia translocation (Ph^1), occurring in human CML[3,4]. The abnormal chromosomes are designated $9q^+$ and $22q^-$; of these, the $22q^-$ chromosome is observed in 92% of CML cases[5]. We investigated the chromosomal location of the human c-*abl*

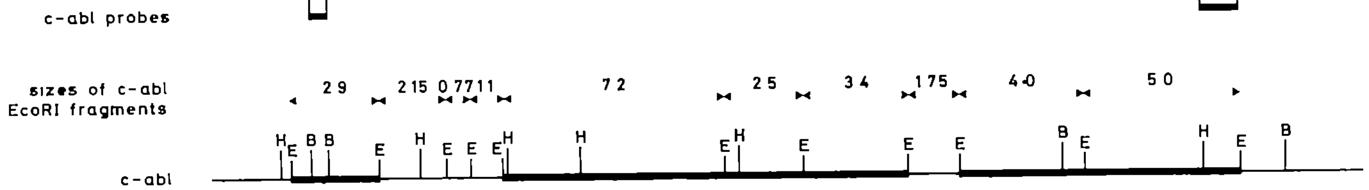

Fig. 1 Restriction enzyme map of the human c-*abl* region[19]. The upper line of the figure shows the *Bam*HI subclone of A-MuLV; the hatched box presents the long terminal repeat, the solid bar the acquired cellular sequences. Directly beneath the A-MuLV genome, a subgenomic *Pst* 1.7-kb fragment, used as a probe in this study, is shown. Human c-*abl* DNA restriction fragments homologous to v-*abl* sequences are indicated as black boxes and those that show homology to the 1.7-kb *Pst* v-*abl* fragments are designated by P 1.7. The third line shows the human c-*abl* 0.6-kb *Bam*HI and 2.2-kb *Hin*dIII-*Eco*RI probes, which hybridize to 5′ and 3′ c-*abl Eco*RI fragments, respectively. The sizes of all *Eco*RI c-*abl* fragments are indicated on the fourth line. The bottom line represents the restriction enzyme map of the human c-*abl* gene. Restriction enzymes include *Bam*HI (B), *Hin*dIII (H) and *Eco*RI (E). A more detailed characterization of the human c-*abl* locus will be published elsewhere[19].

WESP-2A	–	–	–	–	–	–	+	+	–	–	–	–	–	+	–	–	–	–	–	–	–	–	+	–	–	+	–	×

The origin and details of the initial characterization of the somatic cell hybrids are described in the references listed in the last column. PgMe-25NU and WESP-2A are hybrids obtained from fusions with mouse Pg19 and WEHI-3B cells, respectively. Chinese hamster cell line E36 was used to produce hybrid clones 10CB-23B and 14CB-21A, while Chinese hamster cell line a3 was used to obtain 1CB-17aNU. Chromosome analysis was done using reverse (R) banding with acridine orange, after heat denaturation. At least 16 metaphases were analysed per cell line. The presence of human AKl activity was assayed by cellulose acetate (Cellogel) electrophoresis[27]. This test is inconclusive for the WESP-2A cell line (×), because the expression of AKl was found to be repressed in hybrids derived from fusion with WEHI-3B cells (A.H.M., G.v.K., unpublished results). Chromosome and isoenzyme analyses[22] were performed on the same batches of hybrid cells that were used for the isolation of DNA.

gene in cases of CML, where the Philadelphia translocation is present. Southern blot analyses with c-*abl* and v-*abl* probes were performed on *Eco*RI-digested DNAs from somatic cell hybrids segregating the 9q⁺ and 22q⁻ chromosomes.

The cell hybrids used here contain a full complement of mouse or Chinese hamster chromosomes and a limited number of human chromosomes. The hybrid cell lines have been obtained by fusion of cells from mouse (Pg 19 and WEHI-3B) or Chinese hamster (E36 and a3) origin with leukocytes from different CML patients and from a normal donor[6,20]. The human chromosome content of these cells is summarized in Table 1 and is based on chromosome analysis. In addition, the hybrid cells were tested for the expression of human adenylate kinase-1 (AK1) enzyme activity, a marker localized proximal in band 9q34 (ref. 21). This latter test was necessary to exclude the possibility of hidden (broken or rearranged) chromosome 9 fragments in the 22 and 22q⁻ cell lines.

Detection of the human c-*abl* restriction fragments in hybrid cell DNAs is often inconclusive using v-*abl* probes, because the human sequences are present in submolar amounts (20–50%) and also because many of the human c-*abl* restriction fragments electrophorese in close proximity with strongly hybridizing mouse or Chinese hamster fragments. To obtain molecular probes with specificity for human c-*abl* sequences, two restriction fragments were isolated from subclones of c-*abl*-containing cosmids, with homology to the presumptive 5′ and 3′ proximal *Eco*RI fragments of c-*abl*. These are 2.9 and 5.0 kb, respectively, in size (Fig. 1). After hybridization and washing to high stringency (0.1 × SSC)[12], the 5′-terminal 0.6-kb *Bam*HI probe and the 3′-terminal 1.1-kb *Hin*dIII–*Eco*RI probe cross-

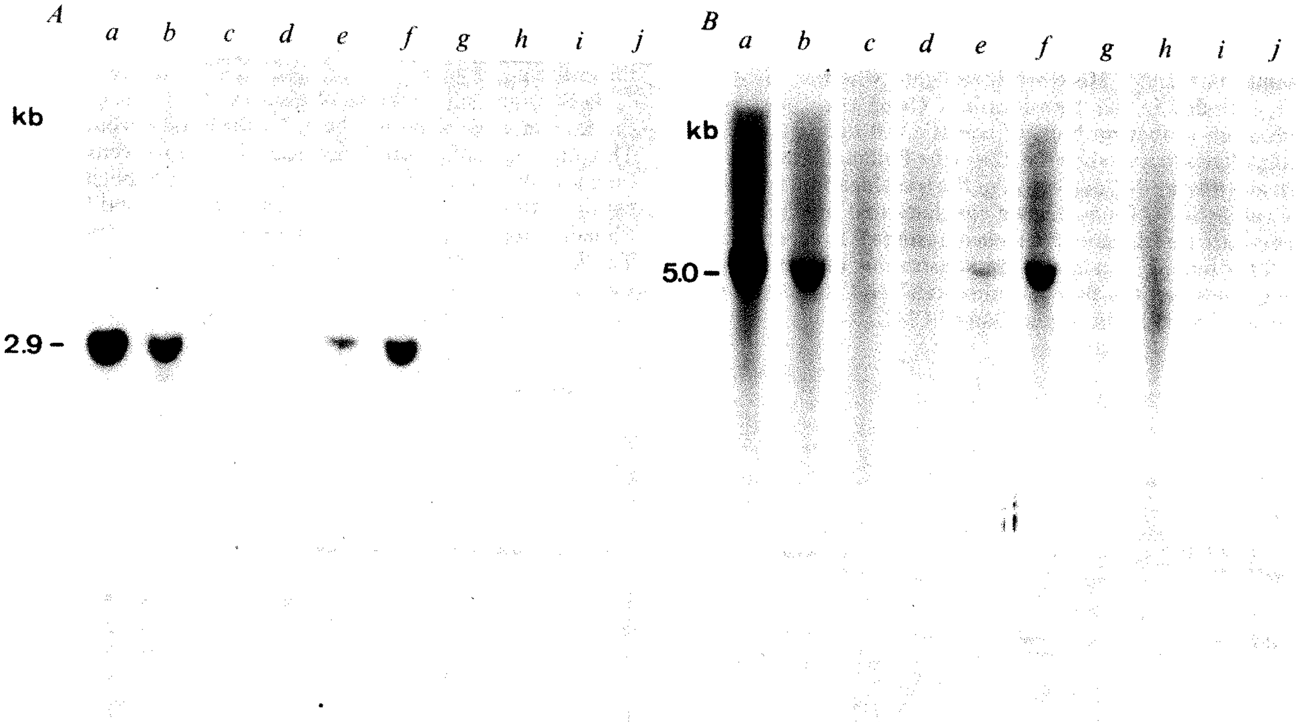

Fig. 2 Localization of human c-*abl* sequences on the Philadelphia chromosome, using hybrid cell lines and human c-*abl* probes. *A*, detection of the human 5′ end 2.9-kb *Eco*RI c-*abl* fragment in DNA from *a*, human placenta; *b*, 10CB-23B (chromosome 9); *c*, PgMe-25NU (chromosome 22q); *d*, 14CB-21A (chromosome 9q⁺); *e*, 1CN-17aNU (chromosome 22q⁻); *f*, WESP-2A (chromosome 22q⁻); *g*, mouse Pg19; *h*, Chinese hamster E36; *i*, mouse WEHI-3B; *j*, Chinese hamster a3. *B*, detection of the 3′-end 5.0-kb *Eco*RI c-*abl* fragment in DNAs as indicated in *A*(*a*–*j*). The derivations of all these cell lines and their complements of human chromosomes are summarized in Table 1.

Methods: All cell lines used in this experiment were grown in large batches (10^7–10^8 cells) and DNA was prepared as described by Jeffreys and Flavell[28]. *Eco*RI-restricted DNAs (10 μg per lane) from human placenta, hybrid cell lines, mouse and Chinese hamster fusion partners were electrophoresed on 0.7% agarose gels. *Hin*dIII and *Hin*dIII–*Eco*RI-digested λ DNAs were included as molecular weight markers (not shown). After blotting to nitrocellulose, the filters were hybridized to the 0.6-kb *Bam*HI c-*abl* (*A*) or 1.1-kb *Hin*dIII–*Eco*RI c-*abl* (*B*) restriction fragments described in Fig. 1. Hybridization and washing procedures (to 0.1 × SSC at 65 °C) were carried out according to the method of Bernards and Flavell[23].

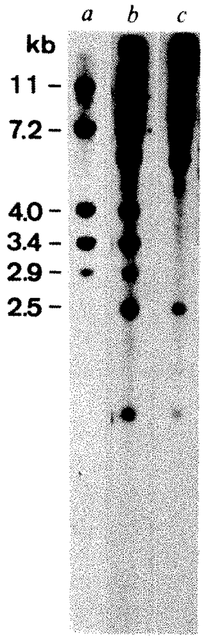

Fig. 3 Localization of human c-*abl* sequences on the Philadelphia chromosome, using a $22q^-$ somatic cell hybrid and a v-*abl* probe. *Eco*RI-digested DNAs (10 μg) from human placenta (*a*), hybrid WESP-2A (*b*) and mouse WEHI-3B cells (*c*) were hybridized with the 1.7-kb *Pst* v-*abl* fragment (Fig. 1), as described in Fig. 2 legend. After hybridization, the filters were washed to 1 × SSC at 65 °C. Molecular weights of human c-*abl* fragments were deduced from co-electrophoresed *Hin*dIII and *Hin*dIII–*Eco*RI-digested λ DNA markers.

hybridize to a very low extent with mouse or hamster c-*abl* sequences. Figure 2*A* shows an example of a hybridization experiment with the 0.6-kb *Bam*HI probe. This Southern blot illustrates hybridization of *Eco*RI-restricted DNAs of hybrid cell lines containing chromosomes 22, 9, $9q^+$ or $22q^-$. As controls, hybridization of the probe with human placenta DNA and DNA from the mouse and Chinese hamster fusion partners is shown. It is clear that the 2.9-kb *Eco*RI fragment, detected in human placenta DNA, is also present in the lanes containing DNA from the hybrid cell lines 10 CB-23B (chromosome 9), 1CB-17a NU and WESP-2A (both containing chromosome $22q^-$). The band is not detected in lanes containing DNA from PgMe-25Nu (chromosome 22), 14CB-21A (chromosome $9q^+$), Pg19 and WEHI-3B (mouse controls) or E36 and a3 (Chinese hamster controls). Analogous results are obtained when the same *Eco*RI-digested DNAs are hybridized to the 3′-terminal 1.1-kb *Hin*dIII–*Eco*RI probe (Fig. 2*B*). The 5.0-kb *Eco*RI fragment is detected only in DNA from human placenta and from hybrid cell lines containing chromosome $22q^-$ or 9.

The above results show that both the 5′ and 3′ ends of the c-*abl* gene are translocated to chromosome $22q^-$. Because all other c-*abl* *Eco*RI fragments, which hybridize to v-*abl* sequences, are flanked by the 2.9-kb and 5.0-kb *Eco*RI fragments, it seems highly probable that these fragments are also included in the translocation to the Philadelphia chromosome. To test this possibility directly, hybridization was performed using a 1.7-kb *Pst* v-*abl* probe (Fig. 1). Because of the problems with v-*abl* probes indicated above, only WESP-2A, the hybrid containing the most $22q^-$ sequences (50% of the molar amount), was tested. As shown in Fig. 3, the viral probe detects human *Eco*RI c-*abl* fragments of 11, 7.2, 4.0, 3.4, 2.9 and 2.5 kb (weakly). Of these fragments, the 11-kb band has been shown to map outside the main human c-*abl* locus[19] and will not be considered here. The human 2.9-, 3.4-, and 4.0-kb c-*abl* fragments are readily detected in the WESP-2A DNA. In contrast, the 7.2-kb *Eco*RI fragment can only be seen in a short exposure of this filter (not shown), due to spill-over of radiation from strongly hybridizing mouse c-*abl* fragments in this area. The 2.5-kb *Eco*RI human c-*abl* fragment co-migrates with a mouse fragment of similar size and thus cannot be identified in this analysis.

The hybrid cell lines containing the $9q^+$ and $22q^-$ chromosomes examined in the present study, were obtained from fusion experiments with CML cells from three different individuals. Therefore, we conclude that in the Philadelphia translocation a fragment of chromosome 9 is translocated to chromosome $22q^-$ and that this fragment includes the human c-*abl* sequences. This finding establishes that the translocation is reciprocal, a general assumption which is now demonstrated unequivocally. Moreover, the data map the human c-*abl* sequences distal to AK1 (not translocated to $22q^-$, 6, 20) on chromosome 9. The most interesting aspect is that it raises the possibility of involvement of the human c-*abl* gene in the generation of CML.

In principle, the chromosomal translocation associated with CML could lead to elevated levels of c-*abl* expression which, by analogy to the c-Ha-*ras* gene in bladder carcinoma, would induce malignant transformation[24]. Elevated levels of c-*abl* expression could be the result of coupling of the gene to an enhancer sequence present on chromosome 22 or, alternatively, the gene could be linked to a strong promoter of another gene. To test these possibilities, we have initiated studies to clone the c-*abl* gene from the $22q^-$ chromosome using WESP-2A DNA and a cosmid vector system. Finally, it is of interest that in some CML patients variant Ph^1 translocations are observed, in which the participation of chromosome 9 cannot be detected by classical cytogenetic analysis[3,5]. In another group of CML patients the Ph^1 translocation appears to be completely absent[25]. We are now investigating whether the c-*abl* gene is translocated to chromosome 22 in these cases also.

These studies were initiated as part of a collaborative effort with W. F. Bodmer; his helpful discussions throughout the work are greatly appreciated. We also thank F. Grosveld for important contributions to this study, R. A. Flavell for useful suggestions, Ton van Agthoven, Gail T. Blennerhassett and Pam Hansen for technical assistance and Ad Konings and Rita Boucke for help with the preparation of the manuscript. The work was supported by the Netherlands Cancer Society (Koningin Wilhelmina Fonds) and under NCI PHS contract NOI-CO-75380. C.R.B. is a recipient of a fellowship from the Deutsche Forschungsgemeinschaft.

As is typical of all β-thalassaemias[1], the erythroid cells of individuals with the variant haemoglobin E ($\alpha_2\beta_2{}^{26\mathrm{Glu}\rightarrow\mathrm{Lys}}$) exhibit a quantitative deficiency in their content of β-globin (in this case β^E-globin) and its messenger RNA[2,3]. To determine the molecular basis of this phenotype, we have investigated the structure and expression of cloned β^E-globin genes. We report here that the complete nucleotide sequence of a β^E-gene revealed the expected GAG → AAG change in codon 26 but no other mutations. Expression of β^E-globin genes introduced into HeLa cells revealed two abnormalities of RNA processing: slow excision of intervening sequence-1 (IVS-1) and alternative splicing into exon-1 at a cryptic donor sequence within which the codon 26 nucleotide substitution resides. These results demonstrate a disturbance in the expression of the β^E-gene attributable solely to the exon mutation—a novel mechanism for gene dysfunction.

We first examined the nucleotide sequences of β^E-globin genes to determine whether there were two mutations, one in codon 26 and another elsewhere in the gene causing a reduction of mRNA level, or only a single mutation. We studied two different cloned β^E-globin genes that were distinguishable by their intragenic DNA polymorphisms[4]. Underproduction of β^E-globin in individuals bearing either of these two gene types suggests a close relationship between the protein/mRNA deficiency and the exon mutation. The complete DNA sequence of one of the β^E-globin genes (β_1^E), determined by the method of Maxam and Gilbert[5], revealed the expected codon 26 change (GAG → AAG) and four previously identified intragenic polymorphisms[4], but no other substitutions. Partial DNA sequencing of the other β^E-gene (β_2^E) also showed the codon 26 change and a single intragenic polymorphism[4]. Unless a common extragenic mutation were associated with these apparently independently derived β^E-genes, these sequence data indicate that the codon 26 change must be directly related to the underproduction of β^E-mRNA.

The expression of the cloned β^E-globin genes linked to Simian virus 40 (SV40) sequences in a miniplasmid[6] was studied after their introduction into HeLa cells. In this transient expression system, transcripts of the normal β-globin gene are efficiently synthesized and appropriately processed[6-8]. In all experiments we compared transcripts of the two β^E-globin genes with those of a normal gene. Cells were collected either 24 or 48 h after transfection and RNA was analysed by Northern blot analysis[9] and S_1 nuclease mapping[10] using a variety of labelled DNA probes. Both β^E-globin genes directed synthesis of near normal amounts of 9S β-globin RNA (not shown). S_1 nuclease mapping of total cell, or fractionated cytoplasmic and nuclear, RNAs revealed two striking abnormalities of β^E-RNA processing. First, the steady-state level of RNA containing IVS-1 sequences was increased (Fig. 1). Second, a fraction of β^E-transcripts was alternatively spliced (Figs 1, 2); in our hybridization conditions this abnormal product represented 5–8% of the total, a value confirmed by primer extension analysis using an exon-2 fragment.

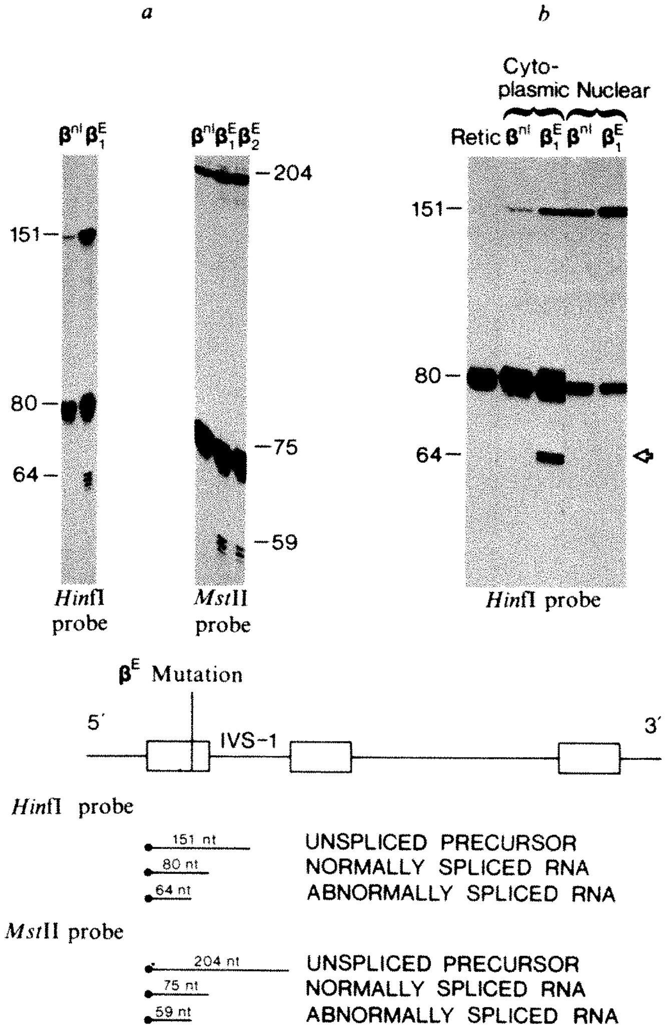

Fig. 1 Slow and alternative processing of β^E-RNA transcripts. β^E-globin genes of frameworks 1 (β_2^E) and 3 (β_1^E)[4,16] were cloned in bacteriophage Charon 28 as described previously and subcloned as a 3.7-kilobase (kb) *BglII/PstI* fragment in the miniplasmid πSV40plac[6]. These β^E-gene subclones and a normal (nl) β-globin gene oriented identically in the same expression vector, were transfected to subconfluent HeLa cells as described by Treisman *et al.*[6]. Total cellular RNAs (*a*) were isolated by repeated guanidine HCl extractions and phenol extraction at 24 h (left) and 48 h (right) after transfection. Cytoplasmic and nuclear RNA fractions (*b*) were prepared from cells 24 h after transfection as described by Favaloro *et al.*[17]. The 3′-end-labelled, single-stranded DNA probes indicated were prepared from β^E-globin gene DNA by filling in 5′-overhangs with ^{32}P-dXTPs (each at 600 Ci mmol^{-1}) using the Klenow function of *Escherichia coli* DNA polymerase I and isolation of the anti-sense strand[5]; 25 μg total or cytoplasmic and 10 μg nuclear RNAs plus DNA probe were denatured in hybridization buffer[17], incubated at 37 °C for 20 h, and then treated with 1,000 U ml^{-1} S_1 nuclease (Sigma) at 37 °C for 40 min. Reticulocyte globin mRNA (6.5 ng) was assayed in parallel as a control. Protected DNAs were electrophoresed in urea–8% acrylamide gels at 2,000 V for 2 h; the gels were then exposed to X-ray film with intensification. Hybridization of the RNA and DNA probe at 51 °C rather than 37 °C led to a marked reduction in protected fragments 59 or 64 nucleotides (nt) long due to instability of short RNA–DNA hybrids at this temperature in formamide buffer (data not shown). Identical S_1 nuclease mapping results (shown above) were obtained with probes prepared from both normal and β^E-gene DNA. Note the presence of alternatively or abnormally spliced RNA in the β^E-RNA samples and the 3–5-fold increase in unspliced material relative to normal. The 64-nucleotide DNA fragment was clearly visible in the nuclear sample on the right on the original autoradiogram, as indicated by the open arrow.

Alignment of the novel protected DNA fragment observed in these S_1 mapping experiments with sequencing tracts of the probe assigned the alternative splice site to an exon-1 donor-like[11,12] sequence, GTG↓GTAAGG, that spans the codon 26 mutation itself (Fig. 2). The normal sequence of this portion of exon-1, GTGGTGAGG, resembles donor (or 5′) splice sites[11,12]. This site is not used in splicing normal gene transcripts

0028–0836/82/510768—02$01.00

(Fig. 1), but is employed in processing RNA transcripts of three different β-thalassaemic genes having substitutions in or near the IVS-1 splice junction (R. A. Treisman *et al.*, in preparation). Activation of this cryptic donor site by the β^E mutation is selective, however, in that additional cryptic sites used in these latter cases are not used to process β^E-transcripts. The cryptic splicing site generated by the codon 26 mutation apparently has sufficiently enhanced affinity with the splicing apparatus to allow it to compete with the normal donor site and retard IVS-1 excision. Additional S_1 nuclease mapping studies (not shown) revealed use of the normal IVS-1 acceptor and IVS-2 donor and acceptor sites in processing β^E-transcripts. The alternatively spliced β^E-RNA cannot encode normal globin due to loss of a portion of the exon as well as production of a downstream in-phase terminator in the processed product. Thus, the HeLa cell experiments demonstrated that β^E-precursor RNA is processed both slowly and alternatively (Fig. 3).

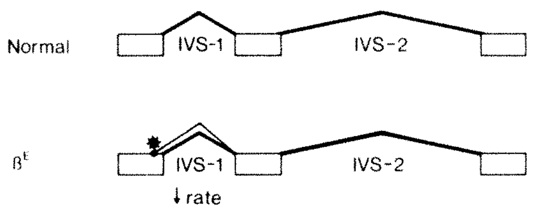

Fig. 3 Splicing patterns of normal and β^E transcripts in HeLa cells. Normal RNA is spliced exclusively from the ends of the exons as depicted. IVS-1 of β^E-RNA transcripts is removed slowly and alternative splicing into exon-1 near the β^E-mutation (asterisk) occurs. We have used the compilations of normal sequences of donor sites reported by Chambon[11] and Mount[12] to estimate the relative affinities of potential splicing sites. The relevant sequences seem to include three nucleotides preceding the invariant GT and four nucleotides thereafter. We have merely summed the number of genes reported in each compilation with a specific nucleotide at each of these positions for the sequences of the normal 5'-IVS-1 splice site, and the normal and β^E cryptic sites; using the listing of Chambon[11], the sums are 489, 448, and 468, respectively. A 'score' of 583 is the maximum possible. From the listing of Mount[12], values of 758, 577, and 622 are obtained with a maximum of 913. Overall, the codon 26 substitution makes the cryptic site of the normal more favourable as a splice site, although still not as strong as the normal site.

The *in vivo* situation in erythroid cells may be more complex than that in HeLa cells due to potential quantitative differences in mRNA metabolism. In total bone marrow RNA of one haemoglobin E homozygote, we have found little, if any, alternatively spliced steady-state β-RNA (not shown). However, in other thalassaemias where alternative splicing occurs as the predominant or only mode of processing of mutant globin transcripts in heterologous cells, alternatively spliced RNAs are detectable at comparatively low levels *in vivo*, probably due to their instability in erythroid cells[6,8,13,14]. Therefore, the apparent absence of such a species from steady-state β^E-bone marrow RNA does not necessarily signify a different processing pattern in erythroid cells, but does prevent full assessment of the contribution of abnormal processing to underproduction of β^E-mRNA. Previously, cytoplasmic instability of β^E-mRNA in erythroid cells has been proposed as another basis for the thalassaemic phenotype[15]. We have observed variable and extensive fragmentation of β^E-mRNA isolated from reticulocytes, but not bone marrow cells, that is consistent with these previous data. However, as most globin is produced in marrow rather than peripheral cells, the contribution of peripheral cytoplasmic instability of β^E-mRNA to decreased β^E-globin synthesis is also unclear. The difficulties in reconciling the results of the surrogate genetic experiments in HeLa cells with those in erythroid cells may largely reflect the rather mild deficit in expression of the β^E-globin gene.

The deleterious effect of a nucleotide substitution in an exon on the rate as well as the pattern of processing of a globin RNA precursor is a newly recognized mechanism of gene dysfunction. The cryptic splice site enhanced by the β^E mutation is also mutated in two other globin genes associated with a thalassaemic phenotype. First, in a β^+-thalassaemic gene, a silent T→A substitution in codon 24 has recently been discovered and shown to affect the processing of RNA transcripts in heterologous cells (A. Nienhuis, personal communication). Second, the predicted DNA sequence GTGGTGAGT in exon-1 of a newly described and underproduced β-chain variant, Knossos ($\beta^{27\mathrm{Ala}\to\mathrm{Ser}}$) (D. Loukopoulos, personal communication) seems as favourable as an authentic donor splice site. We anticipate that transcripts of this β-chain variant will also be alternatively spliced at this cryptic site. Taken together, the underproduction of β-globin from three different genes having mutations within the same cryptic splice site strongly suggests that the alternative RNA splicing we have described is of physiological significance. These principles may easily be expanded to account for underproduction of many gene products associated with inherited disease in man.

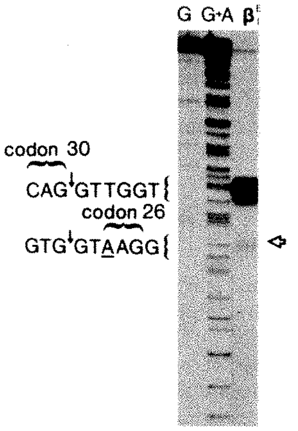

Fig. 2 Location of normal and alternative splices in the β^E gene sequence. Cytoplasmic RNA of HeLa cells transfected with the β^E_1 gene was analysed by S_1 nuclease mapping with the 3'-labelled *Hin*fI probe. G and G+A sequencing reactions[5] of the probe were electrophoresed in parallel lanes. The corresponding sequence of the mRNA strand is shown on the left with the splicing sites indicated by the GT rule[11]. The underlined A in codon 26 is the mutated nucleotide in the β^E-mRNA.

We thank R. Treisman and T. Maniatis for the πSVplac expression vector, the normal β-gene subclone, and for advice and assistance in all aspects of the expression system. We also thank D. G. Nathan for discussions regarding this work. S.H.O. is the recipient of a Research Career Development Award from the National Heart, Lung, and Blood Institute, NIH. This study was supported by grants from the NIH and the March of Dimes-Birth Defects Foundation to S.H.O. and H.H.K.

The deletion in a type of δ^0-β^0-thalassaemia begins in an inverted *Alu*I repeat

Sergio Ottolenghi & Barbara Giglioni

Centro di Studio per la Patologia Cellulare, Istituto di Patologia Generale, Università di Milano, 20133 Milano, Italy

In hereditary persistence of fetal haemoglobin (HPFH) and δ^0-β^0-thalassaemia, increased levels of fetal haemoglobin (HbF) are found in adult individuals. HbF production is particularly noticeable in the former condition in which HbF levels of 20–40% are found in heterozygous patients, as opposed to 5–20% in δ^0-β^0-thalassaemia[1]. In a minority of these cases, no obvious abnormalities have been found in the globin gene region by DNA mapping[2–6], indicating that small deletions or perhaps even point mutations in critical DNA sequences in the globin gene cluster may be responsible for these conditions. However, most cases of HPFH and δ^0-β^0-thalassaemia are associated with extensive deletions in the globin gene cluster[2–4,7–14]. Genetic data[15] and gene mapping investigations[2,4,10] provided some evidence for the location of a regulatory area, whose deletion results in continuing activity of γ-globin genes in adults, in a DNA region between the $^A\gamma$- and δ-globin genes, possibly 3–4 kilobases (kb) 5′ to the δ gene. The precise nature of these sequences is of great interest, because it might help elucidate the molecular mechanisms regulating globin gene expression during development. Recently, Jagadeeswaran *et al.* cloned[16] the DNA encompassing the region of a gene deletion in a type of HPFH[2,10] and showed[16] that the 5′ end point of the deletion lies in the middle of an *Alu*I repetitive DNA sequence[17,18]. We have now cloned the corresponding region from the DNA of a δ^0-β^0-thalassaemia patient[4] and we report here that the deletion ends in a different *Alu*I sequence, ≃700 nucleotides 3′ to the *Alu*I repeat involved in the HPFH deletion, and in the opposite orientation.

The isolation and characterization of the δ^0-β^0-thalassaemic DNA clone will be described elsewhere (B.G. and S.O., in preparation). Figure 1 shows a restriction endonuclease map of the human non-α-globin gene cluster in the region of the $\delta^0\beta^0$ deletion end point. This occurs ~3.8 kb 5′ to the δ-globin gene. Previous analyses[19,20] demonstrated the existence in this area of a pair of repetitive DNA sequences, belonging to the *Alu*I family, pointing in opposite directions and separated by ≃700 base pairs (bp) of non-repetitive DNA.

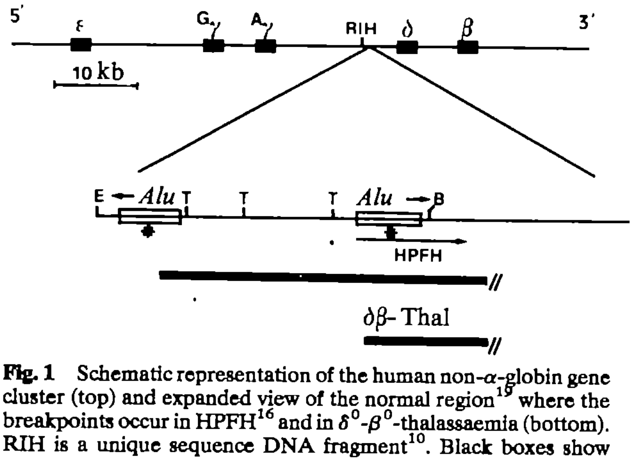

Fig. 1 Schematic representation of the human non-α-globin gene cluster (top) and expanded view of the normal region[19] where the breakpoints occur in HPFH[16] and in δ^0-β^0-thalassaemia (bottom). RIH is a unique sequence DNA fragment[10]. Black boxes show the deletions, short arrows indicate the polarity of the *Alu*I repeats, and the long arrow the transcriptional unit[20]. Asterisks mark the position of sequences homologous to origins of replication of mammalian viruses[17]. E, *Eco*RI site; T, *Taq*I site; B, *Bgl*II site.

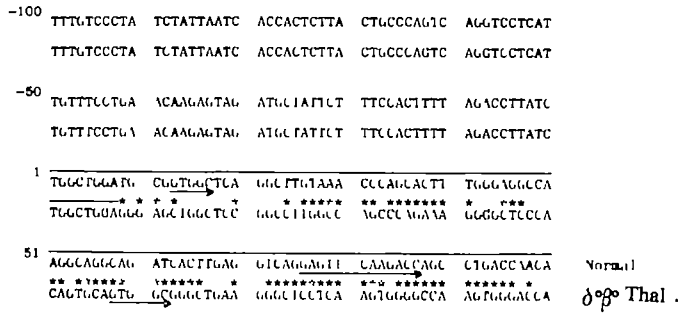

Fig. 2 Comparison of the normal DNA sequence (upper line) with that of DNA across the 5′ end point of the deletion in δ^0-β^0-thalassaemia (lower line). The normal *Alu*I sequence (from nucleotide 1 onwards) is from ref. 20. Asterisks show where the nucleotides of the two sequences differ. Solid lines overlie nucleotides corresponding to *Alu*I DNA. Arrows underlie consensus sequences, possibly involved in specifying transcriptional initiation sites[20,21].

Fine restriction mapping of our clone (S.O. and B.G., in preparation) demonstrates normal bands from the *Eco*RI site to the most 3′ *Taq*I site; we therefore sequenced the δ^0-β^0-thalassaemic DNA 3′ to this *Taq*I site and compared it with the normal DNA sequence (Fig. 2). The two sequences show perfect homology in a 100-nucleotide long fragment. This is followed by an eight-nucleotide sequence in δ^0-β^0-thalassaemic DNA that is identical to the beginning of the normal 3′ *Alu*I repeat; beyond this point the δ^0-β^0-thalassaemic DNA continues into a G-rich region having little homology with the normal *Alu*I sequence. Thus, the $\delta^0\beta^0$ deletion almost completely removes the 3′ *Alu*I sequence, leaving intact the 5′ repeat and non-repetitive DNA in between. In contrast, in the HPFH type sequenced by Jagadeeswaran *et al.*[16], the entire 3′ and part of the 5′ *Alu*I sequence are absent.

HPFH heterozygotes produce during adult life considerably more HbF than δ^0-β^0-thalassaemic heterozygotes. According to the model proposed by Huisman *et al.*[15] (see also refs 2, 4, 10), deletion of an unidentified regulatory sequence between the $^A\gamma$- and δ-globin genes is sufficient to cause a high level of persistent activity of γ-globin genes *cis* to the defect. Thus, comparison of the different deletion 5′ end points in HPFH[16] and δ^0-β^0-thalassaemia identifies the 5′ *Alu*I repeat and/or non-repetitive DNA connecting it to the 3′ *Alu*I repeat as possible candidates for such a key regulatory role. This region is absent from all deletion-type HPFH reported so far, but is present in δ^0-β^0-thalassaemias. (The type of δ^0-β^0-thalassaemia in which expression of the $^G\gamma$ gene exclusively is found[10], is the only apparent exception to this rule. Here, the deletion removes both *Alu*I repeats, but also extends to the $^A\gamma$ gene, thus limiting HbF synthesis; it is probably better considered as a γ-δ-β-thalassaemia.) Although confirmation of the possible regulatory role of this region will require the study of additional HPFH and δ-β-thalassaemias, it is interesting that this region includes sequences for which many different functions have been postulated[17,18]. Here, we only mention that the 3′ *Alu* repeat is transcribed '*in vitro*' by DNA polymerase III[20]. Although the presumed starting site of transcription[20] (position 1 in Fig. 2) is intact, the deletion in δ^0-β^0-thalassaemia removes the internal 'control' region thought to be essential for transcription[20,21]. As nothing is known of their '*in vivo*' transcription, it is premature to speculate about possible roles of the transcription of these sequences in normal and pathological expression of globin genes; however, note that the almost total loss of the 3′ *Alu* repeat in this δ^0-β^0-thalassaemia only slightly changes the phenotype relative to other δ-β^0-thalassaemias in which this region is intact[4]. Finally, attention should also be given to possible effects of distant sequences 3′ to the β-globin gene which are brought by the deletion into direct contact with the *Alu*I repeats; these sequences, which differ between δ^0-β^0-thalassaemic and HPFH DNA (Fig. 2 and ref. 16) are presently

0028–0836/82/510770—02$01 00

being located (in collaboration with R. Flavell) by mapping studies and their structure is being analysed.

The mechanism generating the deletion is unknown, but some clue to its understanding may be provided by the sequence of the δ^0-β^0-thalassaemia clone around the breakpoint. In normal DNA the octamer, TGGCTGGA, at the beginning of the *Alu*I sequence is followed, after a five-nucleotide spacer, by a dodecamer, TGGCTCAGGCTT, including a modified version of the former sequence. In δ^0-β^0-thalassaemic DNA, the octamer is intact and is followed, after a six-nucleotide spacer obviously different from the normal one, by a dodecamer which differs at only two positions from the normal one. The normal sequence, by misaligning with a slightly different distant sequence, might thus act as a 'hotspot' for non-homologous recombination, leading to the large deletion observed. Such a mechanism was recently demonstrated in a prokaryotic system[22]. Cloning of the normal counterpart of the distant sequence should allow us to confirm this mechanism for our case.

We thank Drs A. Viotti and A. Spena for help with the sequence work and for discussions, Professor G. F. Gaja for continuous interest in and support of this work, and R. Mantovani for technical assistance. This investigation was partially supported by Progetto Finalizzato Medicina Preventiva, CNR grant 81.00422.83 to S.O.

The presence of papillomaviruses in epithelial-derived cancers from several animal species[1–3] has led to the speculation that these viruses may also have a pathogenic role in the development of certain human carcinomas, particularly those associated with the anogenital tract[4]. Recently, human papillomavirus (HPV) DNA has been detected in epithelial-derived cancers, both cutaneous[1,5] and metastatic[5], from patients exhibiting the rare, chronic flat wart disease, epidermodysplasia verruciformis (EV). Except for patients exhibiting this chronic wart syndrome, the association of HPV genomes with human epithelial cancers has not been demonstrated[6]. In an attempt to delineate the association and possible involvement of papillomaviruses with human anogenital carcinomas, we have begun an analysis of these cancers for the presence of HPV-specific nucleotide sequences by using highly sensitive hybridization procedures capable of detecting distantly related papillomaviruses at low copy number. Here we demonstrate the presence of HPV DNA in several types of anogenital tumours: Bowenoid papulosis, carcinoma *in situ*, and verrucous carcinoma. These data indicate that HPV can be detected in several types of premalignant and malignant tumours, supporting the contention that this group of viruses may be involved in the development of certain types of human epithelial-derived cancers.

We have used the Southern blot hybridization procedure to search for HPV DNA in three types of anogenital tumours verrucous carcinoma, which is a form of invasive squamous cell carcinoma; carcinoma *in situ*; and Bowenoid papulosis, which is histologically identical to but biologically distinct from carcinoma *in situ*. Total cellular DNA was extracted from tumour tissue as described previously[5] and analysed by the Southern blot hybridization technique[7]. The HPV DNA probes used in these analyses included HPV-EV and HPV-5 obtained from patients with epidermodysplasia verruciformis[5,8], and HPV-6 obtained from a patient with condylomata accuminata, a form of anogenital wart[9]. The HPV DNAs were molecularly cloned into pBR322 and the recombinant plasmids were labelled with ^{32}P *in vitro* by nick-translation[10] resulting in specific activities of 5×10^8 c.p.m. μg^{-1}. Because of the apparent lack of homology between different types of HPV in stringent hybridization[11,12], conditions of reduced stringency were used in these analyses. In such low stringency conditions, any specific type of HPV will hybridize to any of the other known varieties of

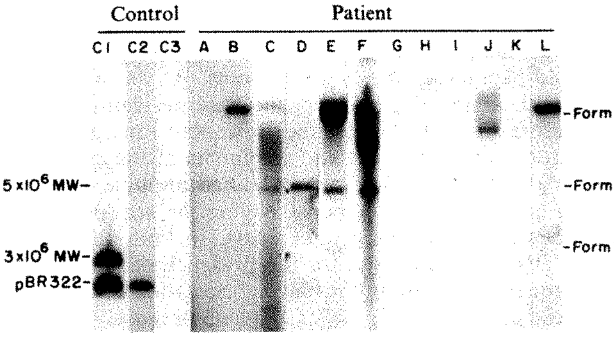

Fig. 1 Detection of HPV DNA in tumour tissue. Total cellular DNA was extracted from tumour tissue as previously described[5]. The DNA was electrophoresed through 1% agarose gels and transferred to nitrocellulose filters by the method of Southern[7]. The filters were dried at 80 °C under vacuum for 2 h and hybridized in conditions of low stringency. The HPV used as probe in these conditions was an HPV species that exhibits homology (~36%) with HPV type 3 in stringent conditions (ref. 8 and M. Green, personal communication) and which for brevity is referred to here as HPV-EV. The filters were pre-hybridized at 37 °C for 24 h in hybridization solution containing 500 μg ml^{-1} depurinated salmon sperm DNA, 0.1% each of bovine serum albumin, Ficoll 400 and polyvinylpyrrolidone, 20 mM sodium phosphate *p*H 6.8, 1 M sodium chloride, 0.1% SDS, and 30% formamide[11]. Fresh hybridization solution containing nick-translated ^{32}P-HPV-EV probe (containing both cloned *Bam*HI fragments (5 ng probe per ml solution; 2.5×10^6 c.p.m. ml^{-1} and 10% dextran sulphate) was added to the filters and incubated at 37 °C for 20 h. Filters were washed three times in 2×SSC *p*H 7.0 (0.3 M sodium chloride, 0.03 M sodium citrate), 0.1% SDS, and 0.1% Na pyrophosphate at room temperature and for an additional 4 h in 3× SSC *p*H 7.0, 0.1% SDS, and 0.1% Na pyrophosphate at 40 °C. Filters were dried and autoradiographed at −70 °C with an intensifying screen. Lane C1 contains 10 pg of the 3.0-megadalton fragment of the HPV-EV DNA used as probe that had been cleaved from the pBR322 plasmid with *Bam*HI; also present is the remaining 10 pg of pBR322. Lane C2 contains 100 pg of linear HPV-5 that was prepared from a plasmid composed of HPV-5 and pBR322. The plasmid was cleaved with *Bam*HI and the fragments separated by agarose gel electrophoresis. The linear HPV-5 band was cut out of the gel and the DNA was electroeluted from the agarose as previously described[5]. The lower band is a trace amount of pBR322 that remained in the preparation. Lane C3 contains 10 μg of cellular DNA from a hyperkeratotic lesion. Lanes A–L contain 5–10 μg of cellular DNA from the corresponding patient. The DNA in lane D was cleaved with *Bam*HI, while the remaining cellular DNA samples were not treated with restriction endonucleases.

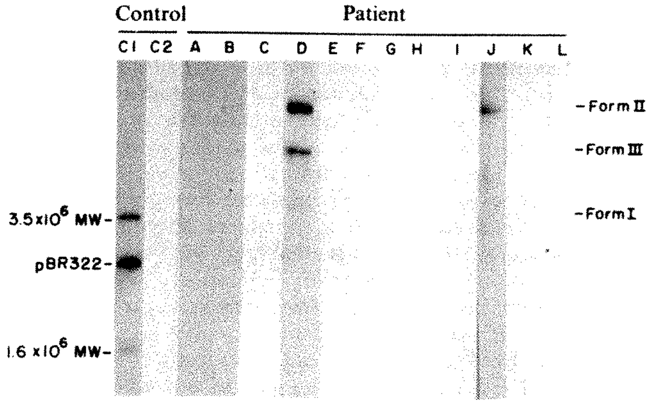

Fig. 2 Hybridization of DNA from tumour tissue with ^{32}P-HPV-6 in stringent conditions. DNA was prepared, electrophoresed and transferred to nitrocellulose as described in Fig. 1 legend. The stringent hybridization conditions were similar to those described in Fig. 1 with the following differences: (1) the pre-hybridization and hybridization solutions contained 50% formamide; (2) the hybridization was carried out at 40 °C; (3) after the room temperature washes, the filters were washed for an additional 4 h in 0.4× SCC *p*H 7.0, 0.1% SDS, 0.1% Na pyrophosphate at 50 °C; and (4) the probe used was nick-translated pBR322-HPV-6. Lane Cl contains 10 pg of the 3.5-megadalton fragment and 10 pg of the 1.6-megadalton fragment of HPV-6 DNA; each has been cleaved from the pBR322 plasmid with a *Bam*HI and *Eco*RI double digestion. Lane C2 contains 10 μg of cellular DNA from a hyperkeratotic lesion. Lanes A–L contain 5–10 μg of cellular DNA from the corresponding patient.

HPV by virtue of distantly conserved nucleotide sequences[12,13]; using these conditions, no hybridization can be detected between DNA from any HPV type and simian virus 40 or BK DNA[13]. The sensitivity of our low stringency hybridization procedure allowed detection of as few as six copies of heterologous HPV genome equivalents per diploid cell (see Fig. 1, lane C2).

Tumour samples were analysed from two patients with Bowenoid papulosis. One of the patients (A) was a 35-yr-old female with a single tumour on the external genitalia. Four years before the detection of the Bowenoid tumour she was treated for anogenital warts and carcinoma of the cervix. The second patient (B), a 33-yr-old male, had multiple Bowenoid tumours on the shaft of the penis. Neither he nor his wife had a previous history of anogenital warts. In both cases, when cellular DNA was analysed for the presence of HPV-related DNA sequences by Southern blot hybridization in conditions of reduced stringency (T_m −40 °C), we observed HPV-specific nucleotide sequences migrating in an identical manner to unintegrated forms of HPV DNA (Fig. 1).

The verrucous carcinoma samples were obtained from a 61-yr-old female (C) with a history of squamous cell carcinoma of the cervix and a verrucous carcinoma on the perineum, and from a 17-yr-old male (D) with a penile verrucous carcinoma. These tissue samples showed unintegrated HPV DNA in less stringent hybridization conditions (Fig. 1).

Eight vulvar carcinoma *in situ* tissue samples were also obtained for analysis. Four out of eight DNA samples from these patients contained HPV-related DNA when analysed by hybridization in less stringent conditions (see Fig. 1, patients E–L).

Due to the association of HPV-5 DNA with carcinomas from patients exhibiting epidermodysplasia verruciformis[1,5], we also tested DNA extracts from many of the verrucous carcinomas and carcinomas *in situ* with labelled HPV-5 in stringent conditions where we could detect as little as 0.1 viral genome copy per cell genome equivalent. With these conditions we were unable to detect any HPV-5-related sequences (Table 1). Moreover, we have tested these tumour DNAs for nucleotide sequences homologous to an HPV (type 6) that is associated with anogenital papillomas[14] and find most of these tumours negative for HPV-6-related sequences (Fig. 2, Table 1).

The viral DNA extracted from each patient's tissue was found to be of typical HPV genome size (~5 megadaltons) with no evidence of any subgenomic fragments, as has been shown in carcinomas from patients with epidermodysplasia verruciformis[5]. Based on the electrophoretic mobility of form I (covalently closed circular), form II (nicked circular) and form III (linear) viral DNA, most of the viral DNA obtained from these tissues seems to be unintegrated although we cannot completely exclude the possibility of integrated viral sequences using this detection technique. Sufficient HPV DNA was not available to perform restriction endonuclease mapping to type the HPV species in these tumours.

From the Southern blot hybridization analysis presented here, it is clear that HPV-specific nucleotide sequences are present in several different anogenital tumour samples. Our ability to detect as few as six copies of heterologous HPV genome equivalents per cell genome using conditions that facilitate hybridization with heterologous HPV types enhanced our ability to detect HPV sequences. This technique is thus more sensitive than that used in a recent study in which carcinomas were analysed for the presence of HPV DNA in stringent hybridization conditions which only detected HPV DNA closely related to that of the radiolabelled HPV DNA probe[6]. Moreover, we have detected HPV DNA in anogenital cancers that were previously thought to lack HPV[14]. At present it is unclear what, if any, is the specific involvement of HPV in the development of these anogenital tumours. The 12 patients analysed in this study exhibited three clinical syndromes each characterized by either benign, premalignant or malignant transformation of anogenital skin. The presence of HPV DNA in these tumours suggests but does not implicate a pathogenic

Table 1 Summary of lesions examined and detection of HPV-related sequences

Lesion	Patient	Age	Site	Less stringent (^{32}P-HPV-EV)	Stringent ^{32}P-HPV-5	^{32}P-HPV-6
Bowenoid papulosis	A	35	Vulva	+	ND	–
	B	33	Penis	+	ND	+
Verrucous carcinoma	C	61	Vulva	+	–	–
	D	17	Penis	+	–	+
Carcinoma *in situ*	E	20	Vulva	+	–	–
	F	40	Vulva	+	–	*
	G	27	Vulva	–	–	–
	H	44	Vulva	–	–	–
	I	42	Vulva	–	ND	–
	J	77	Vulva	+	ND	+
	K	32	Vulva	+	–	–
	L	84	Vulva	–	ND	–

+, HPV sequences detected; –, HPV sequences not detected; ND, not determined.

* When the small amount of viral DNA seen in stringent conditions (Fig. 2, patient F) is compared with the large amount seen in less stringent conditions (Fig. 1, patient F), there are two possible explanations: either there is more than one type of HPV present in this tumour and HPV-6 represents a very low percentage of the total viral DNA or there is such a high concentration of viral DNA in the sample that low level cross-hybridization has occurred. As neither possibility can be conclusively excluded by the data presented, we prefer not to classify the HPV type present.

role for papillomaviruses. Since several patients had a previous history of wart disease it is possible that latent virus or viral DNA remained in the skin of these patients after eradication of the wart disease. In support of this contention is the identification of HPV DNA in normal skin of some patients with EV disease (R.S.O. *et al.*, in preparation). On the other hand, the history of previous wart disease was not a criterion for choosing the patients. Our original interest was in patients with multifocal tumours which clinically resembled warts. These studies, therefore, also include patients that exhibited no previous history of wart disease, and we similarly found HPV DNA associated with their tumours. It is conceivable that either these patients may have had small lesions that were undetected or they were infected subclinically. Nevertheless, our studies indicate that the entire spectrum of anogenital tumours, from benign to malignant, can carry free HPV DNA genomes. More patients must be studied to understand the prevalence of this association. Restriction endonuclease mapping and other molecular studies must be performed to characterize the virus type. As many patients with anogenital wart disease do not develop genital malignancies, other factors may be involved. Host immunity, co-carcinogens and infection with other virus groups may also have a pathogenic role with HPV in the process of malignant conversion.

We thank C. Kosman for typing this manuscript. This work was supported by grants from the NIH (CA 25462) and the Minnesota Leukemia Task Force.

Note added in proof: After submission of this manuscript, Green *et al.* reported the presence of HPV-specific DNA in several different anogenital carcinomas[8].

Localization of the normal allele of T24 human bladder carcinoma oncogene to chromosome 11

The development of DNA-mediated gene transfer techniques[1,2] has made it possible to identify transforming genes present in certain human tumour cells. Such genes have been shown to induce morphological transformation when used to transfect suitable assay cells[3–10]. Recently a transforming gene has been isolated by molecular cloning techniques from the T24 (ref. 11) and EJ (ref. 12) human bladder carcinoma cell lines[10,13,14]. This bladder carcinoma oncogene has been shown to be of human origin, less than six kilobase pairs (kbp) in size, and closely related to the *onc* genes (v-*bas* and v-*ras*) of BALB and Harvey murine sarcoma viruses[15–17]. These transforming retroviruses arose in nature by transduction of cellular genes from mouse and rat cells, respectively[18]. To understand better the relationship of the T24 oncogene with other human cellular genes, we have determined the chromosomal location of its normal allele within the human genome. We show here that it is carried on chromosome 11 in normal cells.

Somatic cell hybrids were constructed between various human cell lines and either mouse or Chinese hamster cells. Such hybrid cells segregate human chromosomes and will only show the presence of the corresponding human gene when the relevant chromosome has been retained. Thus, comparison of the presence or absence of the human gene with the known karyotype of a number of somatic cell hybrids allows assignment of the gene to a particular human chromosome.

To map the normal allele (c-*bas*) of the T24 oncogene, a 3.0-kbp *Sac*I subfragment containing v-*bas* related sequences[17] was used as a probe. As shown in Fig. 1, this probe detected a 20-kbp fragment in *Eco*RI-cleaved human placenta DNA. Using stringent hybridization conditions, hybridization with related genes present in either mouse or Chinese hamster DNA was not found. The 20-kbp fragment was observed in 4 of 18 somatic cell hybrids (Fig. 1) in one series (Fig. 2) examined. Analysis of two additional series of hybrid cell lines (*b* and *d*, Table 1) showed that hybridization to the T24 probe correlated only with the presence of human chromosome 11.

To confirm assignment of the normal allele of the T24 oncogene to chromosome 11, six hybrid cell lines were subcloned, including three lines which contained chromosome 11. This procedure allowed further human chromosome segregation. Spontaneous loss of chromosome 11 was observed in many subclones (14/32) of the three parental lines originally retaining this chromosome. However, detection of T24 oncogene sequences by molecular hybridization in each series of subclones correlated with the presence of chromosome 11 (Table 1*c*) and therefore the normal human homologue of the T24 oncogene can be unambiguously assigned to this chromosome.

Previously assigned markers carried on human chromosome 11 include lactate dehydrogenase A (LDH-A) and esterase-A4 (EsA4) which have been regionally localized to the short arm (11p1203–11p1208) and proximal portion of the long arm (11cen–11q22) respectively[19]. The presence of the normal allele of the T24 oncogene correlated with expression of human LDH-A in all hybrids. However, human EsA4 was detected in four additional hybrid lines (Table 1*b*) which did not contain this oncogene or human LDH-A. The chromosome 11 break point in these four lines has not been determined by karyotypic analysis, but a fragile site has been previously described on the proximal portion of the long arm (11q13) of chromosome 11 in cultured cells[20]. Our results currently exclude the distal portion of the chromosome 11 long arm as the locus of the T24 transforming gene.

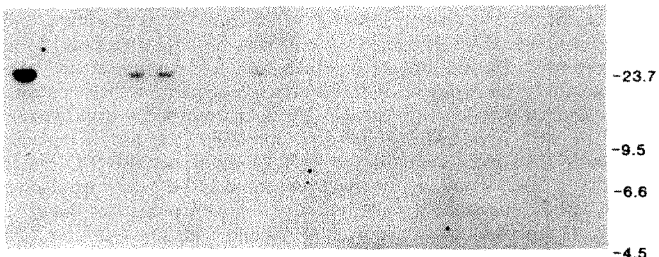

Fig. 1 Hybridization of the normal allele of the T24 oncogene to *Eco*RI-digested DNA from human–Chinese hamster somatic cell hybrids. Human and Chinese hamster control DNAs were run in lanes 1 and 2 respectively. Lanes 3–20 contained DNAs from 18 somatic cell hybrids of series *a* (Table 1). After size-fractionation by electrophoresis, DNAs were transferred to nitrocellulose filters and hybridized to a nick-translated 3-kbp cloned insert derived from the normal allele of the T24 oncogene[17]. The positions of *Hin*dIII-digested λ DNA fragments are indicated on the right.

Normal cellular alleles of the T24 oncogene can be transforming genes in a variety of conditions. The transduction of mouse or rat cell homologues of this gene by retroviruses had led to the creation of BALB- and Harvey-murine sarcoma viruses. Recent studies have shown that the normal human gene itself can be manipulated *in vitro* by the addition of retroviral long terminal repeat sequences so as to acquire transforming activity[21]. Only minor genetic alterations lead to activation of this gene as a transforming gene in T24 bladder carcinoma cells. By restriction mapping and heteroduplex analysis, the normal gene could not be distinguished from the T24 oncogene in the region required for transforming activity[17], excluding any major insertion, deletion or major rearrangement of sequences. In fact, recent findings indicate that a point mutation affecting the twelfth amino acid residue from the amino terminus of the T24 oncogene product accounts for its transforming activity[22,23].

The potential importance of *onc* genes of transforming retroviruses for understanding basic mechanisms involved in malignant transformation, has recently led to the chromosomal mapping of several of these genes. Thus, the human homologue of v-*sis*, the *onc* gene of simian sarcoma virus, has been assigned to chromosome 22 (refs 24, 25) while *mos* (ref. 26), *fes* (refs 27, 28), *myb* (ref. 27), and *abl* (ref. 28) have been mapped to chromosome 8, 15, 6 and 9, respectively. Our chromosomal assignment of the normal allele of the T24 ocncogene to chromosome 11 represents the first mapping of a cellular gene shown to be activated as a transforming gene in a human tumour. Knowledge of the locations of this and other *onc*-related genes has obvious importance for determining the relationship, if any, between known chromosomal aberrations in naturally occurring tumours and oncogenes found on such chromosomes.

Table 1 Segregation of the normal allele of the T24 oncogene with specific human chromosomes

Series	Total hybrids	T-24 allele positive	% Discordancy	
			Chromosome 11	Other chromosomes
a	18	4	0	≥11
b	19	3	0	≥16
c	56	18	0	≥16
d	22	10	0	≥23

Assignment of the normal allele of the T24 oncogene to human chromosome 11 is based on analysis of the segregation of this gene with specific human chromosomes in human–rodent somatic cell hybrids. Cell pellets were simultaneously prepared for DNA isolation and isoenzyme analyses from three series of somatic cell hybrids (*a*, *b*, *d*) and subclones of six hybrid cell lines (*c*). The 3.0-kbp *Sac*I probe was hybridized to nitrocellulose filters containing *Eco*RI-digested, size-fractionated cellular DNAs. The human chromosomes present in each hybrid cell line were determined from starch gel electrophoretic analyses[31,32] of isoenzyme markers that have been previously assigned to each of the human chromosomes[19] as described[24]. Preparation and chromosomal analysis of hybrid series *a* (ref. 33) and *d* (ref. 24) have been reported. Hybrid series *b* is similar to *a*, and it represents hybrid lines isolated after fusing well-characterized human fibroblasts containing a balanced translocation between the X cxhromosome and chromosome 14 with *hprt*$^-$Chinese hamster fibroblast[33]. *c* Series denotes subclones of six hybrid cell lines from *d*. Concordancy refers to either retention or loss of both a human chromosome and the gene from each line, whereas independent segregation of a chromosome and the gene represents discordancy. Detection of the normal allele of the T24 oncogene could be correlated with the presence or absence of human chromosome 11 in all hybrid cell lines. The minimum discordancy between segregation of all other human chromosomes and the oncogene is shown with the following exceptions: *a*, 0% and 6% discordancy with chromosomes 13 and 16, respectively; *b*, 0% and 11% discordancies with chromosomes 3 and 4 and chromosome 10, respectively; *c*, 5, 7, 9 and 9% discordancies with chromosomes 22, 1, 6 and 9, respectively. The long arm of chromosome 11 alone (EsA4 marker) did not segregate concordantly with the T24 oncogene in series *b* (see text).

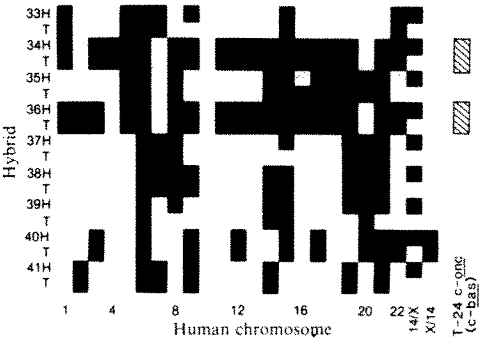

Fig. 2 Distribution of specific human chromosomes in human–hamster cell lines of *a* (Table 1). Hybrids were isolated after fusing well characterized human fibroblasts (GM0073) containing a reciprocal X;14 translocation with *hprt*$^-$ Chinese hamster fibroblasts and cloning each independent line twice[33]. Individual hybrid cell lines are represented on the ordinate and H or T indicates expansion of that cell line in HAT (100 μM hypoxanthine, 1 μM amethopterin and 16 μM thymidine) or 50 μM 6-thioguanine, respectively. Specific human chromosomes are represented on the abscissa. Solid boxes indicate the presence of a particular human chromosome in a hybrid line, and open boxes indicate absence of the chromosome. The presence of the normal allele of the T24 oncogene is shown by hatched boxes in the last column.

The relevance of human chromosome 11 to cancer-associated genes has previously been restricted to the association of a deletion on this chromosome with Wilms' tumour, a malignant renal tumour of children[29]. The deletion has been localized to 11p13 by binding techniques[30]. This deletion could lead to loss of some normal function or to a rearrangement that might result in gene activation. Although we cannot yet precisely localize the T24 oncogene to this specific region, it is tempting to speculate that an association may be involved since the oncogene segregates concordantly with a short arm (11p) marker and discordantly with a long arm (11q) marker for this chromosome.

We thank Debra Keithley and M. C. Otey for technical assistance, Gail Taff for preparation of this manuscript, and Holly Fuhrer for photography. Human GM0073 cells were provided by the Institute for Medical Research (Camden, New Jersey, USA).

Low Ca^{2+} impedes cross-bridge detachment in chemically skinned *Taenia coli*

K. Güth & J. Junge

Department of Physiology II, University of Heidelberg,
Im Neuenheimer Feld 326, D-6900 Heidelberg, FRG

Muscle force is generated by cycling cross-bridges between actin and myosin filaments. In smooth muscle, cyclic attachment and detachment of cross-bridges is thought to be induced by a Ca^{2+}- and calmodulin-dependent myosin light chain kinase which phosphorylates myosin. The relaxation that occurs after Ca^{2+} removal is usually ascribed to dephosphorylation of myosin by a phosphatase as non-phosphorylated myosin is unable to form force-generating criss-bridges[1]. Recently, Dillon *et al.*[2] claimed, however, that dephosphorylation of attached cross-bridges may impede cross-bridge detachment, thus forming so-called 'latch bridges'. Here we present evidence that after a Ca^{2+}- and calmodulin-induced contraction of chemically skinned guinea pig *Taenia coli*[3], the rapid removal of Ca^{2+} impedes the detachment of the myosin cross-bridges from the actin filament; force can then be maintained without energy consumption. The extremely slowly detaching cross-bridges which maintain the force after Ca^{2+} removal may indeed correspond to the 'latch bridges' mentioned above.

The Ca^{2+}-jump technique[4] allows the Ca^{2+} concentration to be changed in small bundles of chemically skinned muscle fibres within fractions of a second. Compared with this time scale, the mechanical response in chemically skinned *T. coli* is much slower; the broken line marked ±Ca^{2+} in Fig. 1 shows the time at which the Ca^{2+} concentration was changed from $<10^{-8}$ M to 10^{-5} M and vice versa. The force generated by the fibre (solid line) shows a marked delay in response to Ca^{2+}. It is conceivable that this delayed relaxation was due to an internal viscoelasticity independent of the actin–myosin interaction. Such a 'passive' viscosity would probably not be affected by inorganic phosphate. However, the relaxation was markedly accelerated after addition of 6 mM inorganic phosphate to the incubation solution.

Figure 1 shows that in contrast to the force (solid line), the ATPase activity (open circles) decreased immediately after Ca^{2+} removal. Thus, the high force maintained after Ca^{2+} removal must be ascribed to non-cycling but attached and force-maintaining cross-bridges. The simplest interpretation of our findings is that the rate constant of the cross-bridge detachment is similar to the rate constant of tension decrease, that is, $\sim 0.1\ \mathrm{min}^{-1}$. From the ATPase activity (Fig. 1) and the total myosin concentration in this type of muscle[5], the turnover rate for the actin–myosin interaction was estimated to be $\sim 0.25\ \mathrm{s}^{-1}$ at 10^{-5} M Ca^{2+}, assuming that all myosin molecules are interacting with actin and that they interact with only one head at the same time. As ATP splitting requires a complete cross-bridge cycle (including detachment and reattachment of the cross-bridge), the turnover time of the cross-bridge cycle must be longer than the time needed for cross-bridge detachment. Thus the detachment rate of the cross-bridges after Ca^{2+} removal (estimated

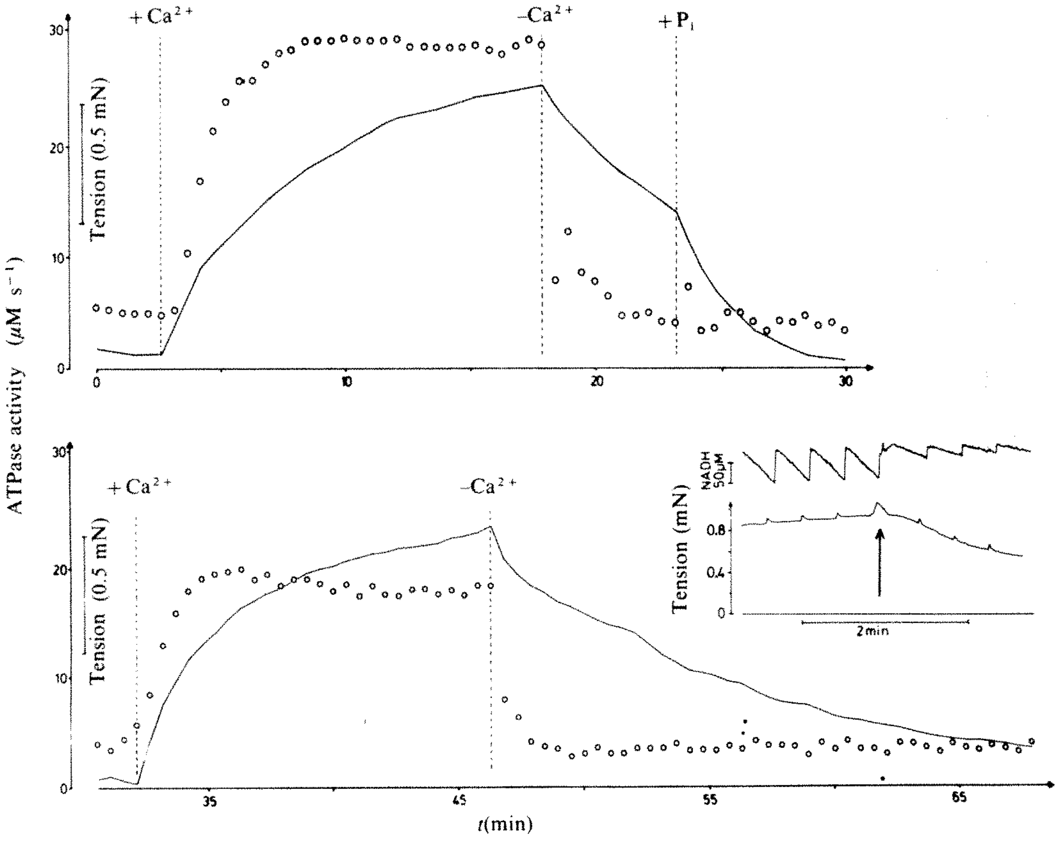

Fig. 1 Force and ATPase activity of chemically skinned *T. coli* from guinea pig. The solid line shows the generated force, the open circles the simultaneously measured ATPase activity (mol ADP l^{-1}, fibre vol s^{-1}). The dashed line marks the time at which the Ca^{2+} concentration was changed from $<10^{-8}$ M to 10^{-5} M (+Ca^{2+}) and vice versa (−Ca^{2+}). The time at which 6 mM phosphate was added to the incubation solution is indicated by the broken line marked P$_i$. The 'tension cost' has a maximum at the start of the contraction (see ref. 9). ATPase activity was measured using an NADH-coupled optical assay method; in this assay the consumption of NADH corresponds to ADP production. A fibre bundle (0.3 mm diameter, length 7 mm) was mounted in a narrow chamber (diameter 0.8 mm) which was perfused with an ATP–salt solution (pH 6.7, $T = 20$ °C) consisting of: 30 mM imidazole, 7.5 mM ATP, 10 mM MgCl$_2$, 1 mM NaN$_3$, 1 mM phosphoenolpyruvate, 4 mM EGTA, CaEGTA, 100 U ml^{-1} pyruvate kinase, 140 U ml^{-1} lactate dehydrogenase, 0.6 mM NADH, 0.2 mM P^1,P^5-di(adenosine-5'-)pentaphosphate, 2 mM dithioerythritol, 0.1 μM calmodulin (for the effect of calmodulin see ref. 3). To measure the NADH consumption, the perfusion was stopped for 30 s (see inset: upper trace, NADH concentration in the chamber; lower trace, force. The time at which the Ca^{2+} concentration was changed from 10^{-5} M to $<10^{-8}$ M is marked by an arrow). The change in the NADH fluorescence intensity with time in both chamber and fibre was recorded with a Zeiss microscope photometer. After the measurement, the chamber was perfused again with fresh solution, and the procedure was repeated.

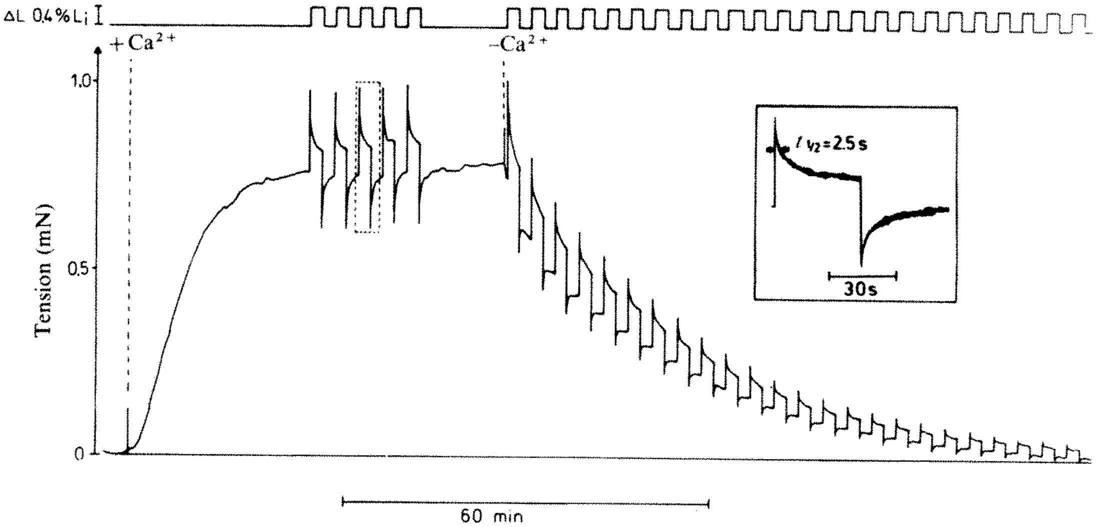

Fig. 2 Force response of a repetitively stretched and released skinned *T. coli*. The upper trace shows the length signal, the lower trace the corresponding force. The broken line marks the time at which the Ca^{2+} concentration was changed from $<10^{-8}$ M to 10^{-5} M (+Ca^{2+}) and vice versa (−Ca^{2+}). The inset shows, with an expanded time scale, the force transient of one stretch–release cycle. Conditions as described in Fig. 1 legend. ΔL, 0.4% L_i = length change as % of the initial length (L_i).

above to be ~0.1 min^{-1}) must be over 100-fold slower than the detachment in the presence of Ca^{2+}. It has been concluded from biochemical studies, however, that ATP may also be split by myosin–S1 being attached to actin[6]. Thus the cross-bridge cycle of attachment and detachment could be much slower than indicated by the rate of the ATP splitting process. To obtain a different estimate for the cross-bridge detachment rate, contracted fibre bundles were stretched and released repetitively (see Fig. 2: upper trace, muscle length; lower trace, the corresponding force). A plausible interpretation of the force transients obtained is that after the length change, the force changes (with a half time ($t_{1/2}$) of ~2.5 s) until the cross-bridges that are attached at the moment of the length change are replaced by others. The kinetics of this process is the same for small stretches and for small releases, indicating that it also reflects the cross-bridge kinetics of the isometric contracting state. If this is so, and if the detachment limits the rate of the force recovery after the length change, then the rate of cross-bridge detachment in the Ca^{2+}-activated state presumably must be greater than ~0.5 s^{-1} (compared with 0.1 min^{-1} after Ca^{2+} removal). The tension recovery following length perturbations after Ca^{2+} removal seems to be slower and less complete (see also Schneider *et al.*[7]). This finding is also consistent with a slow detachment of cross-bridges after Ca^{2+} removal.

The results reported here indicate that after Ca^{2+} removal, cross-bridge detachment occurs much more slowly than in the presence of Ca^{2+}. The absence of Ca^{2+} obviously inhibits not only the myosin cross-bridge attachment to actin but it also impedes cross-bridge detachment from actin (see also 'catch' state in the Byssus retractor[8]). Whether this is a direct effect of the lack of Ca^{2+} or an indirect effect due to dephosphorylation of myosin remains to be determined. In any case, after Ca^{2+} removal, non-cycling cross-bridges or those that are still attached cause the high force to be maintained with very low ATPase activity.

We thank Mrs C. Haist for technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft (grant Gu 160).

Orientation of spin labels attached to cross-bridges in contracting muscle fibres

Roger Cooke*, Mark S. Crowder* & David D. Thomas†

Electron micrographs showing different cross-bridge orientations in different states of muscle fibres, and X-ray diffraction patterns indicating axial cross-bridge disorder in contracting muscle first suggested that force generation in the contracting muscle involved a change in orientation of the myosin heads that form cross-bridges between thick and thin filaments[1,2]. This has been supported by subsequent work; the myosin molecule has the required flexibility for changes in orientation[3,4]. The orientation of muscle tryptophans and of probes attached to the myosin heads of permeable muscle fibres depends on the state of the muscle[5–9]. Recently, fluorescence polarization fluctuations and time-resolved X-ray diffraction patterns have suggested that cross-bridges of a contracting muscle can rotate[10,11]. We have used electron paramagnetic resonance (EPR) spectroscopy to monitor the orientation of spin labels attached specifically to a reactive sulphydryl on the myosin heads in glycerinated rabbit psoas skeletal muscle. Previously, it has been shown that the paramagnetic probes are highly ordered in rigor muscle, with a nearly random angular distribution in relaxed muscle[12]. We show here that during the generation of isometric tension, ~80% of the probes display a random angular distribution as in relaxed muscle while the remaining 20% are highly oriented at the same angle as found in rigor muscle. These findings indicate that a domain of the myosin head does not change orientation during the power stroke of the contractile interaction.

The maleimide spin label (MSL) can be reacted selectively with a reactive sulphydryl on the myosin head (SH$_1$) in a glycerinated rabbit psoas muscle fibre[12,13]. The EPR spectra can be used to determine directly and unambiguously the angular distribution of the probes relative to the magnetic field[12,13]. Here we have used spin labels attached to SH$_1$ to

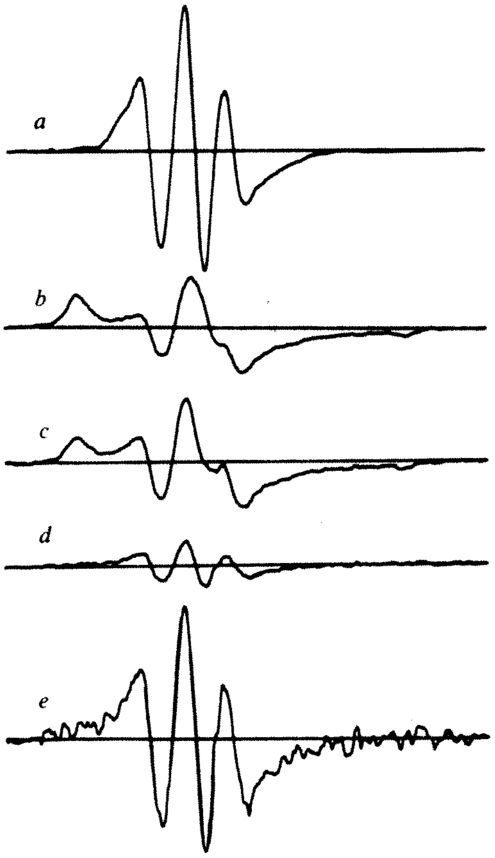

Fig. 1 EPR spectra of spin labels attached to the myosin heads during rigor (*a*), relaxation (*b*) and isometric tension (*c*). Spectrum *d* is a difference spectrum, obtained by subtracting 81% of spectrum *b* from spectrum *c*. This difference spectrum is shown again in *e*, amplified by 5.3 so that it represents the same number of probes as spectra *a–c*. Glycerinated rabbit psoas fibres were labelled with MSL by the procedure of Thomas and Cooke[12] except that the label concentration was increased to 0.5 mM, the *p*H was 6.5, and the duration of labelling was 10 min. Approximately 50–70% of the heads were reacted at the SH_1 as judged by extraction of myosin and measurement of ATPase activity in the presence of EDTA. Spectra were obtained at 24 °C with a Varian E109E spectrometer interfaced to a Northstar computer. The E238 cavity was modified to accept a capillary (1.2 mm inside diameter) parallel to the applied magnetic field. About 100 fibres, in bundles of 5–10, were secured on either end with surgical thread and pulled into the capillary, almost filling it. Solution was allowed to flow past the fibres at 0.3 ml min^{-1} (that is, with a velocity of 2–5 cm s^{-1}), aiding perfusion of the bundles. No differences in the spectra were seen when the bundle size or flow rate was increased or decreased by a factor of 2. Fibres in rigor were bathed in 'rigor buffer' (0.12 M KCl, 5 mM $MgCl_2$, 2 mM EGTA and 20 mM MOPS, *p*H 7.0). Relaxed spectra were obtained by addition of 5 mM ATP, 20 mM CP and 0.4 mg ml^{-1} creatine kinase to the rigor buffer. Contraction was induced by adding 2 mM $CaCl_2$. After contraction the fibres were returned to rigor solution, and data were used only when the reappearance of a well ordered spectrum indicated that sarcomere heterogeneity had not developed during contraction. The baseline for each spectrum is 100 G wide.

investigate cross-bridge orientation during isometric contraction of skeletal muscle.

Figure 1 shows the EPR spectra of MSL-labelled muscle fibres held isometrically in conditions of rigor (Fig. 1*a*), relaxation (*b*) and tension (*c*). The spectrum of fibres in rigor indicates that the probes are highly oriented, with a gaussian angular distribution of 15° (full width at half maximum) centred about an angle of 82 ± 1° with respect to the fibre axis[12]. When ATP is added to relax the fibres, the EPR spectrum shows that the angular distribution of the probes is almost isotropic[12] (Fig. 1*b*). Addition of Ca^{2+} induces tension (see Fig. 1*c*); this spectrum can be shown to be a superposition of the spectra obtained in rigor and relaxation. When 81% of the spectrum in relaxation (Fig. 1*b*) is subtracted from that in tension (Fig. 1*c*), the difference spectrum is identical to that of rigor fibres (Fig. 1*d*, *e*). Subtraction of different fractions (not shown) shows clearly that the correct disordered fraction lies between 75 and 85%. Thus, under isometric tension, 80 ± 5% of the myosin heads have probes disoriented as in relaxed muscle, while the probes on the remaining heads are highly oriented similar to fibres in rigor. The most dramatic aspect of Fig. 1*c* is that no new probe angles, different from those seen in rigor or relaxation, are observed. The resolution of the spectrum is high. If over 5% of the probes assumed a new, well defined angle differing from the rigor angle by >10°, or if over 10% of the probes were less disordered than in relaxation (that is, distributed over <90°) they would have been detected.

A first question which arises from the spectrum of Fig. 1 is whether the 'rigor-like' component of the spectrum obtained during force generation represents a state in the normal cycle of the cross-bridge or whether it is due to some portion of the sample that is in rigor because of an inadequate supply of ATP. We have addressed this question by varying the concentration of ATP or creatine phosphate (CP), and by observing the speed at which small molecules can diffuse into the fibres. Figure 2 shows the fraction of disoriented probes as a function of the ATP concentration. The fraction of disoriented probes approaches 75% as the concentration of the substrate approaches infinity. A similar result was obtained when the concentration of CP was varied. Thus, the myosin heads seem to be saturated with substrate in the conditions used in Fig. 1. The conclusion was further strengthened by several additional experiments. Following a change in the perfusing solution from a rigor solution to a relaxing solution, the spectral changes occurred exponentially with a time constant of 5 s, showing a rapid rate of substrate diffusion into the fibres. If the flow of the perfusing solution was abruptly stopped during contraction, no increase in the rigor component was observed for over 40 s, indicating that the fibres contain sufficient substrate for this

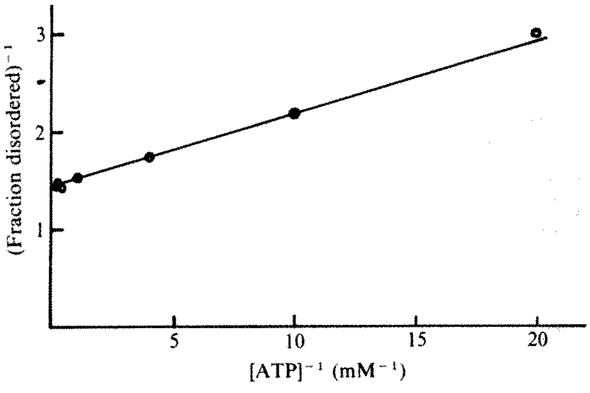

Fig. 2 The fraction of disoriented probes as a function of the ATP concentration over the range 50 μM to 10 mM; conditions are the same as in Fig. 1*c*, except for ATP concentration conditions. The fractions of disoriented and oriented probes are proportional to the heights of the first (P_1) and second (P_2) spectral peaks, respectively. Because a given peak height for P_1 represents twice as many probes as P_2 (see Fig. 1 *a*, *b*), the fraction of disoriented probes is $2P_1/(2P_1+P_2)$. The inverse of this fraction is plotted in Fig. 2, as a function of the inverse of the ATP concentration. If the fraction of oriented probes decreased to zero as substrate increased the data should extrapolate at the ordinate to 1, the value for relaxed fibres. This does not occur, and the extrapolated value shows that ~25% of the probes remain oriented as the substrate concentration approaches infinity.

time period and that the magnitude of the rigor-like component is not due to a balance between the rate of substrate diffusion into the fibres and its consumption.

We conclude that all the myosin heads in our fibres were in the presence of saturating ATP, therefore that the different spectral components corresponded to different states in the force-producing cross-bridge cycle. Thus, in isometric tension, the probed domain in each myosin head spends about 80% of its time in a state with disorientation identical to that of relaxation, and about 20% of its time in a state having an orientation identical to that of rigor. Reaction with the label decreased the active tension of the fibres by ~20%. Further reaction of the fibres with the non-paramagnetic *N*-ethylmaleimide (2 mM) for 2 h eliminated both active tension and the oriented component of the active fibres. Thus, the oriented component seems to represent active cross-bridges, and its magnitude may be decreased by 20% due to the inactivation of some cross-bridges during labelling.

Although the EPR spectra in Fig. 1 report most directly on orientation, they provide information about the fraction of myosin heads attached to actin. Other work, using conventional EPR to measure orientation[12] (as described here), and saturation transfer EPR to measure motion[13-15], have shown that probes are highly oriented and immobile when myosin is attached to actin (in fibres or myofibrils in rigor, or in actomyosin) but are highly disoriented and mobile (on the μs scale) when myosin is detached from actin (in fibres at long sarcomere lengths or in relaxation, or in purified myosin filaments). Saturation transfer EPR experiments on myofibrils show that most of the probes are as mobile during contraction as in relaxation, suggesting that most are detached[13]. Thus, the most straightforward interpretation of the data in Fig. 1 is that during tension generation, the myosin head spends ~20% of its time attached to actin, and that for most of that time the orientation of the probed region is identical to that in rigor. In principal, we cannot exclude the possibility that some of the disordered probes are attached in either relaxation or tension, but this seems unlikely in view of the previous observations that they have the same degree of disorder and motion as in fibres stretched beyond overlap. The fraction of attached heads in contracting fibres has been estimated using various techniques. Fibre stiffness and X-ray diffraction have suggested, respectively, that roughly 70% and 50% of the heads are attached[16,17]. However, values close to that found here are obtained from calculations based on the ATPase activity rate of isotonically contracting frog fibres (ref. 18 and W. Bialek and R.C., unpublished), and from a study of the motion of a myosin-bound spin label[19].

Information on cross-bridge dynamics has been obtained from measurements of the transients in tension or sarcomere length that follow step changes in muscle length[20,21]. Although there are many possible molecular explanations of these and other transient phenomena, they strongly suggest that the predominant attached states during isometric tension occur early in the power stroke, not at the end[20,23]. Nevertheless, our EPR spectra indicate that the predominant probe orientation is identical with that of rigor, the state which is usually assumed to be at the end of the power stroke. These results suggest, therefore, that states early and late in the power stroke have the same probe orientation, that is, the probed region of myosin does not rotate during the power stroke. This is supported by the observation that stress does not alter the orientation of spin labels on myosin heads in rigor fibres, a result which shows that the angle of the spin label is not linked to the force supported by the fibre[24]. It is possible that the probe is oriented relative to the myosin head at such an angle that myosin rotation does not affect the probe orientation, but this is extremely unlikely in light of the high resolution of the rigor-like component of the contracting fibres; neither the centre of the distribution nor its width differs from that of rigor by more than 1°.

There are many different models that fit the conclusion of this study. One possibility is that the entire myosin head maintains a constant orientation during the power stroke, while some other part of myosin shortens; one example of such a model has been proposed[25]. Alternatively, the probed region of myosin may remain rigidly oriented on actin, while another domain of the myosin head does rotate. There is, as yet, insufficient evidence to exclude either possibility.

We thank Drs Manuel Morales, Robert Mendelson and Paul Wagner for illuminating discussions; Marilyn Hersh for help with the manuscript; and Vincent Barnett, Christine Wendt and Toshio Yanagida for assistance with preparations and EPR experiments. Mapping the evolution of biochemistry

Frederic L. Holmes

IN THIS first full-length study of the institutional structures within which the family of sciences known today as "biochemistry" have grown to maturity, Robert Kohler describes the formation, development, and sometimes the decline, of the various administrative organizations within which that field has been practised and taught. Kohler bases his account on an impressive array of unpublished institutional and individual archives; his aim is to reconstruct representative events underlying what he defines as "the changing political map of scientific disciplines".

Beginning with the origins of physiological chemistry in Germany between 1840 and 1900, Kohler recounts how, after a promising start, that field failed to develop independent institutional foundations. The subject was pursued instead within other disciplines such as physiology and pathology. Even though German scientists exerted much of the leadership in biochemical research then and on into the early twentieth century, they failed, according to Kohler, to build a discipline. Equally, in Great Britain physiologists resisted the formation of separate departments of physiological chemistry, even though they regularly hired organic chemists to fill the posts in physiological chemistry. The major exception to this pattern was the Cambridge school of general biochemistry, which Frederick Gowland Hopkins was able to establish in the 1920s with the aid of an outside foundation.

Until the 1930s, Germany and Britain provided most of the leading scientists in biochemistry. The United States remained, with some notable exceptions, a research backwater. Nevertheless Kohler devotes over two-thirds of his book to American biochemistry between 1900 and 1940. His justification for this apparent imbalance is that in the United States biochemists were able to achieve the independence which eluded their counterparts in Europe. Kohler shows in detail how this feat was managed in representative American schools. It was the reform movement in American medical schools at the turn of the century, especially the drive to introduce "scientific" medicine, that provided physiological chemists with their opportunities; and it was, Kohler repeatedly emphasizes, because the biochemists established a "service role" teaching medical students that they were able to command the political and financial backing necessary to maintain departments, to support teaching and research positions, and to find jobs for those they trained. At the same time, most efforts to introduce biochemistry as a broadly-based, biological subject into scientific schools and undergraduate colleges failed for lack of a stable service role.

From Medical Chemistry to Biochemistry: The Making of a Biomedical Discipline. By Robert E. Kohler. Pp.399. ISBN 0-521-24312-2. (Cambridge University Press: 1982.) £22.50, $34.50.

Kohler skilfully uses selective case-histories of prominent medical schools to build up a picture of what he regards as the typical patterns of institutional development. Particular departments which departed from these patterns he treats as "deviant" cases, even though the groups which worked in them included some of the most distinguished and influential leaders in the field. He presents his case-histories in short, well-paced narratives, including lively character sketches of the personalities involved, with entertaining descriptions of the manoeuvres in which they often engaged as "discipline builders" and of the disasters which overcame some of the less capable entrepreneurs.

At his best Kohler writes with a felicitous style; sometimes, however, he resorts to distractingly colloquial language and to deliberately political metaphors, such as "physiologists developed an expansive imperialistic program", and "British physiologists were determined opponents of home rule for physiological chemistry". These phrases are designed to reveal scientists as politically motivated and fundamentally no different from any other self-interest group. Use of such language, however, is a cheap way to make the point. It does so merely by colouring the historical figures with the historian's conception of them, without taking the trouble to demonstrate that these people were not primarily motivated by a commitment to their scientific calling.

Kohler's account, based as it is on extensive archival sources, is convincing. There is reason to be wary, however, about the reliability of some of the factual detail. To take one example, chosen because it is familiar to me, Kohler refers briefly to aspects of the career of Hans Krebs in seven different places in his book. Three of these passages contain mistakes. Kohler says (p.71) that Krebs was given a research position at Sheffield in 1938, whereas the correct date was 1935. He writes (p.326) that Krebs made "a smooth transition from pathology to biochemistry in the mid-1930s"; in fact, Krebs was never a pathologist, and he had been involved in biochemical research since 1926. Finally, in a footnote on p.386, Krebs is described as "one of the first outside Beadle's circle to do biochemical genetics", despite the fact that Krebs was never personally involved in research in that field. These are not trivial errors, for in each case the author is illustrating a general point which depends upon the misinformation in question.

The aim of *From Medicinal Chemistry to Biochemistry* is far more ambitious than simply to map out the institutional setting within which the discipline of biochemistry developed, for Kohler's thesis is

> that biochemists' programmatic conceptions of their discipline were shaped by institutional contexts and relationships, such as channels of recruitment, political alliances, and service roles.

Repeatedly he views "research programmes" as arising from local circumstances, tied to strategies appropriate to success within a particular medical school, chemistry department or other institutional arrangement.

It is certainly true that such local conditions influence the type of science practised within individual organizations, but only in the sense that they define which of the possible niches within the broader research stream a particular local group can attempt to occupy. It is not the local patrons who adjudicate whether the research carried out within their organizations is significant enough to merit recognition; rather it is colleagues pursuing similar problems in other centres — comprising the international community, or "invisible college" of a particular speciality :— who make such judgements. We cannot evaluate the degree to which institutions shape research programmes until we have a thorough grasp of what is being shaped. Kohler touches frequently upon the research areas that the biochemists in his story pursued, but he never penetrates deeply enough into these topics to assess the interplay of influences which directed them.

In Joseph Fruton's masterly *Molecules and Life* (Wiley, 1972) and Marcel

Florkin's more encyclopaedic *A History of Biochemistry* (in *Comprehensive Biochemistry*, Vols 30–33b, Elsevier; 1972–1982) we have two very useful descriptions of the main lines of investigation that have characterized the biochemical family of sciences over the past two centuries. Kohler's work on institutions complements these accounts, but he chooses to dismiss the work of Florkin and Fruton as representative of the allegedly outmoded approach of an earlier generation of "insiders". Without their help, however, and much more besides in the way of detailed studies of specific areas of biochemistry, Kohler's assertions about the shaping force of institutions will remain empty generalizations.

By reconstructing the institutional contexts within which biochemistry developed, Kohler has made progress towards an eventual description of the contours of that subject. A modern scientific discipline is, however, an enormously complex cluster of individual leaders and followers, schools, sub-specialities, literature, methods, concepts, traditions, careers, solved and unsolved problems, evolutionary and revolutionary events, as well as a set of institutional organizations. To understand the interplay of all these factors is a formidable task, the magnitude of which social historians of science have scarcely begun to appreciate. □

Programs for seeing

Oliver Braddick

Computer Vision. By Dana H. Ballard and Christopher M. Brown. Pp.523. ISBN 0-13-165316-4. (Prentice-Hall: 1982.) £33.95, $39.95.

BALLARD and Brown intend their book ". . . both as a senior/graduate level text and as a useful reference to those building vision systems". These are admirable and ambitious goals in a field where most books so far have been symposium proceedings or collections of papers, and where the primary literature tends to be a bibliographic jungle of technical reports and conference contributions.

The authors have certainly succeeded in providing a valuable work of reference. The book contains a compendium of the techniques that have been found useful at every level of computer vision systems. If you need an outline of the different possible tesselations of the image plane, the representation of illuminated surfaces in gradient space, chain codes for boundary representation or graph-matching algorithms, these and much more are presented at a sufficiently basic level that they will make the research literature much more accessible to the student or outsider. The frequent use of concrete examples from the programming of vision problems helps to overcome the risk of daunting abstractions and to make clear that the authors' accounts of some general artificial-intelligence issues, such as production systems and semantic nets, do have their relevance to the specific needs of vision.

The goal of making computer programs that obtain knowledge of the world from optical information can be approached from either end. One approach is the search for operations which are effective in extracting from the optical input that information which purely and reliably conveys the significant properties of the world, stripped of the incidental variations of viewpoint, illumination, noisy imaging processes and so on. The other is to realize the richness of prior knowledge that human beings bring to perceptual tasks, and to seek ways in which programs can efficiently use such knowledge to organize the noisy deluge of optical information.

Both approaches are fairly represented in Ballard and Brown's book. Someone planning a vision system might reasonably ask how far they can expect to take "bottom-up" information extracting procedures, and what kinds of otherwise intractable ambiguities or overloads may be dissolved by the "top-down" application of world knowledge. Certainly this is the sort of issue which those interested in human vision hope will be illuminated by computer vision studies. However, the book is less strong on providing this kind of overview. "Top-down" versus "bottom-up" processing may be too over-arching an issue for much resolution of it to be expected, but similar criticisms could be made on a smaller scale. A wealth of techniques is offered, but rather less evaluation of how well they handle various kinds of problem, or consideration of *why* a particular method should be relatively effective or ineffective. The latter is an ambitious demand; but perhaps a field which is still looking for the necessary organizing principles cannot yet sustain a true textbook.

These problems may be a reflection of a more general tension within computer science: is it the body of guidelines to effective practice which underlies a technology, or the body of results about the nature of the world which constitutes a science? Many people are convinced that there is, in the making, a science of how both artificial and biological vision systems can work: Ballard and Brown provide a rare guidebook to trails on the slopes of this unclimbed peak.

Oliver Braddick is Lecturer in Experimental Psychology at the University of Cambridge.

NEW! NEW!

4th Superb Edition
Prescott & Dunn's

Industrial Microbiology

Edited by Gerald Reed
Vice President, Amber Laboratories USA

The up-to-date guide and reference tool to industrial technology and applications in the microbiology of foods and food ingredients – with a special section on biological production of fuel alcohol.

Macmillan Hardcover 896 pp £42.50
ISBN 0 333 33630 5 1982

Genetic Engineering/ Biotechnology Sourcebook

Never before published! Profiles of 1,529 recent and ongoing genetic engineering/biotechnology research projects funded by 122 US government and non-profit organizations.

Covers research affecting: ★ Pharmaceuticals ★ Medicine and Diagnosis ★ Agriculture ★ Food Processing ★ Energy ★ Chemicals.

Reveals for each project ■ Nature and objectives of research ■ Funding source and money awarded ■ Names and addresses of individual researchers.

Special Yellow Pages reference section – tells you at a glance who's researching what, where, when and how.

Macmillan Softcover 350 pp £52.50
ISBN 0 333 34148 1 1982

Yet more population modelling

Robert H. Smith

Modelling Fluctuating Populations. By R.M. Nisbet and W.S.C. Gurney. Pp.379. ISBN 0-471-28058-5. (Wiley: 1982.) £19.50, $47.50.

THE APPEARANCE of yet another book on population modelling written by yet more mathematicians/physicists/engineers with an enthusiasm for ecology is, on a probabilistic basis, unlikely to arouse much interest amongst ecologists. With a few notable exceptions, such texts are mostly regarded as excuses for mathematical self-indulgence and are seldom read by ecologists, apart from those of us unfortunate enough to be asked to review them. However, *Modelling Fluctuating Populations* is exceptional in more than one way, and provided me with an unexpected pleasure; I enjoyed almost all of the book and found every chapter valuable.

Although there have been many books on mathematical ecology since Lotka's seminal contribution *Elements of Physical Biology* (Williams & Wilkins, 1925), few are memorable. May's *Stability and Complexity in Model Ecosystems* (Princeton University Press, 1973) is an exception and must be regarded as one of the most important books in the field; as well as some new insights into the subject matter of the title, the book provided a lucid account of the mathematical techniques used by physicists to analyse equations of motion. The main shortcoming of May's book was the deliberate omission of stochastic models, apart from the use of Kolmogorov's diffusion equation to represent a particular type of environmental variability.

In *Modelling Fluctuating Populations*, Nisbet and Gurney have given a thorough and rigorous account of the techniques available for investigating the dynamic properties of models, both deterministic and stochastic. Just as important, they devote some space to the problem of formulating the most appropriate mathematical representation of a process. Most ecologists will find the mathematics hard to follow, but not impossibly so; and at least the authors do not pretend that difficulties both in manipulation and interpretation do not exist.

The presentation of text and equations is of a very high quality, but unfortunately the same cannot be said of the lettering of the figures, many of which call for the use of hand-lens — in this respect the book is more suitable for the field ecologist than the theoretician. Some of the worst examples are where material has been taken from other publications and photoreduced (e.g. Figs 2.15 and 2.16), but there are many other such instances among the figures drawn especially for the book (e.g. Figs 2.9, 5.8 and 7.13). It is a pity that an otherwise excellent production is marred by such an elementary but important flaw.

Like many before them, Nisbet and Gurney find themselves in deep water when they try to put their ecological models into an evolutionary context. Stability is a property of populations and is not a direct consequence of natural selection, and Nisbet and Gurney are honest enough to invoke group selection explicitly when they suggest why limit cycles might be rare in nature. Leaving aside the difficult question of what conditions are necessary for group selection to be of any importance, the authors have a clear penchant for point equilibria rather than stable limit cycles, and most of their linear approximations require the existence of a stable equilibrium point. However, they do not shirk the task of coping with non-linearity where necessary as evidenced by their interesting treatment of Nicholson's blow-fly in Chapter 8. This chapter, and the other two case-studies, are very worthwhile and in themselves provide adequate justification for the rest of this excellent book. ☐

Robert H. Smith is a Lecturer in Applied Zoology at the University of Reading.

The evolution of landscapes

J. Rose

Climatic Geomorphology. By Julius Büdel. Pp.528. Hbk ISBN 0-691-08294-4; pbk ISBN 0-691-08295-2. (Princeton University Press: 1982.) Hbk £40.62, $65; pbk £15.31, $24.50.

OVER the past few decades geomorphology in most English-speaking countries has primarily dealt with the interaction between particular surface processes and the resisting surface materials. For the sake of practicality most of these studies have been concerned with isolated problems, river-channel bedforms or hillslope hydrology for example. The results of this work have been summarized in systematic texts such as Sugden and John's *Glaciers and Landscape* (Edward Arnold, 1976) and Schumm's *Fluvial System* (Wiley, 1977).

Similarly, where English-speaking geomorphologists have investigated the evolution of landscapes through time they have largely adopted an interdisciplinary approach within the framework of the Quaternary; again, these studies have been the subject of significant texts such as Goudie's *Environmental Change* (Oxford University Press, 1977) and Bowen's *Quaternary Geology* (Pergamon, 1978). An explanation for the wider span of landform assemblages and integrated landform development has received little attention other than in Pitty's *Introduction to Geomorphology* (Methuen, 1971), and this has been far from widely understood. *Climatic Geomorphology* by Jülius Büdel, now Emeritus Professor of Geography at Würzburg, Germany is an unashamed attempt to remedy this deficiency.

Büdel's view of geomorphology consists of an investigation of the processes involved, which he calls "active geomorphology"; an appreciation of the role and magnitude of contemporary landscape alteration, which he terms "dynamic geomorphology"; and the global stage upon which the processes take place, to which he gives the title "climato-genetic geomorphology". "Climatic geomorphology" is the foundation for all these approaches and is the thesis of this book.

In many respects *Climatic Geomorphology* is a personal expression of over 50 years' geomorphological experience from all regions of the globe. Although there are some distinctive personal traits, such as a degree of contempt for the isolated studies that have dominated geomorphological research in the English-speaking world, it is far from out of date, with some 38 per cent of the references published in the decade before it went to press, and far from parochial with 19 per cent of the references in the English language. The book is divided into three parts: an introductory section which explains the geomorphic processes, interactions and spheres of operation in a concise but illuminating fashion; a main body of text which reviews the global landscape in terms of morphogenetic regions; and a series of case-studies from selected areas to illustrate the principles so developed. This last section gives particular emphasis to aspects of the central European landscape.

To a considerable extent, Büdel's approach to geomorphology, and hence the rationale behind his book, can be understood in terms of his desire to explain the landscape of central Europe with geomorphologically active Alpine mountains and geomorphologically quiescent incised valleys and upland plains. The mountain and glacial morphogenetic zones he considers to be globally ubiquitous and therefore receive little attention. The incised valleys are the goal of his study of "ectropical" regions and the results of fieldwork in Spitzbergen lead him to believe that bedrock disruption and disaggregation by ground ice beneath river channels provide the mechanism for "excessive valley deepening". Although the argument is clear and well illustrated it is, in my opinion, far from convincing and much of the evidence put forward by Büdel for contemporary *erosion* in his research area is not valid, but is the product of contemporary *deposition* in a region of aggrading ground ice. His quest for an explanation for geologically discordant plateaux takes him to the "peritropical" zones of contemporary etchplain development which he sees as the process for the formation of extensive, low-relief plains. To most of the British geomorphologists interested in cold-climate processes his descriptions of weathering and wash processes in humid tropical regions give a most illuminating explanation for our much-abused and little-understood erosion surfaces.

In many ways, Büdel's views must make geomorphologists in the English-speaking world reassess the results of their single-case, analytical studies. For instance, it is interesting to consider if the approach taken by the contributors to Derbyshire's *Geomorphology and Climate* — published in 1976 (by Wiley) one year before *Climatic Geomorphology* appeared in Germany — gives a greater insight into how landforms and landscapes develop, if it achieves less or if it says the same thing in different ways. For what it is worth, my views are that the recent efforts of English-speaking geomorphologists have contributed much that is of significance to their subject, and that much of Büdel's criticism is unjustified. Equally, however, I believe that without the wisdom shown by Büdel's synthesis many of the individual analytical studies will be wasted.

J. Rose is a Lecturer in Geography at Birkbeck College, University of London.

Bonding chemistry unravelled

B.F.G. Johnson

Multiple Bonds Between Metal Atoms. By F. Albert Cotton and Richard A. Walton. Pp.466. ISBN 0-471-04686-8. (Wiley: 1982.) $63.20, £39.50.

I ADMIRE few chemists as much as F.A. Cotton. He has had a long and successful career and became one of the few inorganic chemists to achieve international prominence, both through the excellence of his research and because he can always be counted on to provide a clear description and cogent explanation of his chemistry. He is a highly skilled author and together with Dick Walton has written a classic book on multiple bonds between metal atoms. This (in my opinion) is Cotton's favourite topic and it shows.

The book examines the fundamental chemistry of compounds containing metal-metal bonds with bond orders greater than one. The study of such compounds has contributed much to modern inorganic chemistry. Unravelling the bonding problems provided by their structures has provided a wonderful stimulus to researchers, from which a totally new and exciting branch of chemistry has emerged.

"Introduction and Survey", the first of the eight chapters in the book, provides a fascinating insight into the genesis of this area of research and how it continues to progress. Apart from this and a further chapter devoted to physical, spectroscopic and theoretical results, the book deals with the formation of multiple bonds found between metal atoms (rhenium, molybdenum, tungsten and rhodium), and with their synthesis, structure and chemistry. Each chapter has been carefully sub-divided into small packages of information, thereby providing a concise and easily followed account. By so doing those of us concerned with compiling a succinct lecture course or simply locating information relevant to our own research will have few problems. There is a wealth of good diagrams and tables, the literature survey is first class and the overall standard of production is excellent.

Cotton and Walton have provided a clear insight into the chemistry and importance of multiple metal–metal bonds. They have written a valuable and entertaining mix of chemistry, reminiscence and opinion, and have thereby given us an enjoyable, readable book which is a must for all practising inorganic chemists.

B.F.G. Johnson is Reader in Inorganic Chemistry at the University of Cambridge.

Everyman's guide to molecular cloning

Noreen E. Murray

Molecular Cloning: A Laboratory Manual. By T. Maniatis, E.F. Fritsch and J. Sambrook. Pp.545. Pbk ISBN 0-87969-136-0. (Cold Spring Harbor Laboratory: 1982.) $40 (US), $48 (elsewhere).

FOR ten years the Cold Spring Harbor publication *Experiments in Molecular Genetics* by J.H. Miller has been a popular and reliable reference book for those working with *Escherichia coli* and its phages. I had anticipated that the laboratory manual *Molecular Cloning* would serve a similar role for those using *E.coli* as host and its plasmids and phages as vectors for the cloning and analysis of DNA. The long awaited manual is now available and I expect few readers to be disappointed.

The manual emphasizes both the biological systems and biochemical tools available. Each topic is introduced clearly, though concisely, taking care to equip the reader with some understanding of the systems and techniques he may use. Quite elementary information is included and a motivated, and perhaps green-fingered, novice should be able to start from simple experiments and rise to the more sophisticated technology, given, of course, the availability of a battery of good enzymes. Even here advice is offered about the careful use and preservation of enzymes. Although the volume is a laboratory manual it is not lacking in basic theoretical information, is well supplied with references and is amply provided with clear illustrations.

The authors have covered the predicted range of topics including vector–host systems, gel electrophoresis, isolation of mRNA, cDNA cloning, the construction of gene libraries and the detection and analysis of recombinant molecules. The information is supplemented with useful appendices full of recipes and simple biochemical methods. In some areas the manual is up to the minute, particularly in its presentation of a recombination method for screening bacteriophage lambda libraries for specific DNA sequences. In contrast it denies the usefulness of bacteriophage λ as an efficient means of cloning cDNA despite contrary documentation in the literature early in 1981.

One criticism that I would make of this otherwise excellent manual, a criticism that possibly reflects the pressures of a fast-moving field, is the presence of more errors than one usually associates with Cold Spring Harbor publications. Thus a list of around 20 *E.coli* strains includes at least five mistakes. Some of these — for example, *supF* where it should be *supE* — are likely to confuse the beginner who will assume that he himself, and not the manual, is in error. In similar vein, λ*sep6-lac5* is stated to be exceptional in having the *red* and *gam* genes in its right arm; in fact, it is not exceptional and furthermore, since it is *gam*$^+$ and *red*$^-$ (not *red*$^+$) it may be propagated on a *recA*$^-$ host in the absence of both phage and host recombination systems.

Despite such blemishes I strongly recommend this manual. Those working in the area of molecular cloning, or contemplating doing so, may have received their copy already; others should put their name on the waiting list.

ANNOUNCEMENTS

Appointments

Dr Vincenzo Buonassisi has been appointed deputy director of the W. Alton Jones Cell Science Centre.

President Reagan has nominated **Mr Robert Gilkeson, Dr William Miller** and **Dr William Nierenberg** to serve for six-year terms as members of the National Science Board, the policymaking body of the National Science Foundation.

The British Secretary of State for Foreign and Commonwealth Affairs has appointed the **Hon John D. Eccles** as a member of the board of the Commonwealth Development Corporation for three years.

Professor J. Lloyd and **Mr G. Telling** have been appointed as members of the Food Additives and Contaminants Committee. **Dr W. Elstow**, and **Professor P. Turner** have been re-appointed as members of the Committee.

Mr Nigel Lawson, the British Secretary of State for Energy, has appointed six new directors for Britoil: **Mr Michael Kelly, Mr Larry Tindale, Sir Archie Lamb, Mr Ralph Quartano, Sir Alistair Frame,** and **Sir Kenneth Corfield.**

Dr Paul Winson has been made marketing manager for the Oxford Instruments Group, UK.

Techne (Cambridge) Limited have recently appointed a new sales and marketing manager, **Mr M.B.C. Sharp.** Mr Sharp has taken over the complete marketing function embracing both UK and export sales.

Mr Peter James has been appointed managing director of Fisons scientific equipment division's Australian subsidiary Townson & Mercer.

Awards

The Hammer Prize Foundation has awarded its first $100,000 prize for cancer research to **Ronald Levy** of Stanford University, USA and **George Stevenson** of the University of Southampton, UK. They were cited for their work on monoclonal antibodies in the treatment of B-cell leukaemia and lymphoma.

Three industrialists have been elected trustees of Scripps Clinic and Research Foundation, the biomedical research and health care institution in La Jolla, California. These are **David Clare** president of Johnson & Johnson, **Richard Cramer** chairman and chief executive officer of IMED Corporation and **Gordon Anderson** formerly with Baker International, now in private investments.

Professor Vernon Mountcastle, University Professor of Neuroscience at the Johns Hopkins University School of Medicine, has been awarded the Hermann von Helmholtz Award for distinguished research in the cognitive neurosciences. It is the first to be made by the Cognitive Neuroscience Institute of New York.

The Prize Jury of the Novo Foundation of Denmark has decided to award the Novo Prize 1983 to **Professor Christian Crone** of the Panum Institute, University of Copenhagen. The Novo Prize is given as a reward for a major achievement, medical or otherwise, which may benefit the medical science. Professor Crone receives the Prize in recognition of his great contributions towards the understanding of capillary functions.

The winners of the first EPIC award — Education in Partnership with Industry and Commerce — have been announced. Joint first prize winners are the **University of Oxford** in conjunction with **Oxford Instruments Group of Industries** and the **Heriot-Watt University** with **Edinburgh Instrument Limited.** The Heriot-Watt/Edinburgh Instruments partnership won their prize for the development of gas laser and opto-electronic devices. The Oxford winners will use their prize of £25,000 to further develop scanning techniques that do not use X-rays and other applications of superconducting magnets. Runners up for the EPIC award, all of whom received £2,000, were: **Cambridge University** in conjunction with **TAL Chemicals Company** for their development of a fruit coating to control the rate at which fruit ripens; **Liverpool University** and **Rentokil** for the improved manufacture of Rentokil SupaTimber preservatives and the development of a new process for the manufacture of arsenic acid; **UMIST** and **Froude Engineering Ltd** for the production of new dynamometers, devices used in the development of automative engines; and the **University of Wales** plus **Lion Laboratories** for developments in their 15 year long collaboration over the measurement of alcohol in breath samples.

The only fellowship awarded this year by the British Mental Health Foundation has been won by **Dr Susan Wonnacott,** a biochemist at Bath University. The fellowship, worth £40,000 over a 3-year period, will enable Dr Wonnacott to continue her work on nicotinic receptors in the brain, with a view to investigating Alzheimer's disease, a progressive senile dementia which affects large numbers of elderly people. This condition is characterized by a progressive deterioration of mental function, primarily in thought and memory and secondarily in feeling and conduct.

The Bristol-Myers Award for distinguished achievment in nutritional research has been given to **Dr Elsie May Widdowson** of Addenbrooke's Hospital, Cambridge, UK. It is an annual award of $25,000, and this year is the first time that the award will be given to a researcher from the UK.

The Mullard Award has been presented this year to **Oxford Instruments** for their work on advanced superconducting magnets and associated systems, particularly in the area of Nuclear Magnetic Resonance.

A project to develop credit transfer and improve advice on courses available to students has been launched by the Department of Education and Science. A contract, worth nearly £900,000 over three years, has been awarded to the **Open University** to develop and implement the piloting of a computerised Educational Counselling and Credit Transfer Information Service (ECCTIS) in the South West of England.

The Foulkes Foundation, a registered charity which aims to further medical research, has announced the winners of the Foulkes Foundation Fellowship. The fellowship gives financial support to recently qualified science graduates with research experience who want to study medicine, and medical graduates who want to take a science degree. The successful candidates for 1982 are: **Dr D.S. Blanchard, Dr J.P. Burrows, Dr D.A. Gray, Dr P.M. Matthews, Dr R. Silcock, Mr K.A. Steer, Dr C.-K.V. Tse** and **Dr E. Walker.** Entries for the 1983 awards are invited. Application forms will be available from the Fellowship Registrar in January 1983 and applicants are asked to enclose a stamped, addressed envelope.

Entries are invited for the Prince of Wales Award for Industrial Innovation and Production. The Award was first inspired by His Royal Highness in 1980 and aims to identify promising new products or processes and encourage the inventor or entrepreneur to get them into production and onto the market as soon as possible. It is being organized by The Engineering Council. The closing date for receipt of entries is 28 February 1983. Entry forms and further details may be obtained from: The Engineering Council, Canberra House, 10–16 Maltravers·Street, London WC2R 3ER, UK.

ICI has made an endowment of £10,000 to a trust fund which will be administered by The Royal Society of Chemistry, to organise a biennial symposium on industrial chemistry in memory of Dr Alfred Spinks, CBE.

The Ciba Foundation is establishing a bursary scheme linked to the Ciba Foundation symposia. This scheme will enable young scientists to attend Ciba Foundation symposia and subsequently spend a period in the laboratory of one of the major participants. The bursars will be selected from laboratories or institutes not represented at the symposium. The successful bursar's travel, accommodation and other expenses will be met by the award.

Two National Institute on Ageing teaching nursing home grants, totalling $7.43 million over five years, have been made available to support research on geriatric health problems in a nursing home setting. The National Institute on Ageing is part of the US Public Health Service. These are the first grants of their kind to be proposed.

Nominations are invited for the Marconi International Fellowship. Nominees should be individuals whose work in the fields of communication science and technology exemplifies the technical creativity and concern for human welfare of Guglielmo Marconi. The deadline for nominations is 15 April 1983. Final selection of the recipient will be made in October 1983 and the successful candidate will receive £35,000. The Fellowship Selection Committee will give special attention to the identification of emerging fields of communications science and technology. Nominators are asked to specify why they believe that the nominee has made innovative contributions to a field of research or technology of growing future significance.

British Gas has set up a Teaching Fellowship at Cambridge University attached jointly to the Engineering and Chemical Engineering Departments. **Mr. N.K. Macfadyen** has been appointed as its first holder.

Meetings

10-12 January, **The Brain, Biochemistry and Behaviour,** Florida (Ms M. Hack, 355 St Paul's Avenue, Staten Island, NY 10304, USA).

16-22 January, **International Seminar on Human Waste Management,** Bangkok, (Ms T. Liamzon, Seminar Co-ordinator, PO Box 24-130, Bangkok 10240, Thailand).

20 January, **Innovation Conference,** Manchester (Mr J. Jackson, Shirley Institute, Manchester M20 8RX, UK).

January, **Conference on the Palaeo-environment of East Asia,** Hong Kong (R.O. Whyte, University of Hong Kong, Centre of Asian Studies, Pokfulam Road, Hong Kong).

6-10 February, **Third Annual Congress for Recombinant DNA Research,** Philadelphia (Mr E. Ruffing, Scherago Associates, 1515 Broadway, Tenth Floor, New York, NY 10036, USA).

6-10 February, **Second Annual Congress for Hybridoma Research,** Philadelphia (Mr E. Ruffing, Scherago Associates, 1515 Broadway, Tenth Floor, New York, NY 10036, USA).

6-10 February, **"Biotech '83",** Philadelphia (Mr E. Ruffing, Scherago Associates, 1515 Broadway, Tenth Floor, New York, NY 10036, USA).

7-11 February, **Optical Methods in Engineering Metrology,** Colchester (The Liaison Officer, Laser Workshop Courses, University of Essex, Colchester C04 3SQ, Essex, UK).

7-11 February, **Course in Gear Design,** Sheffield (Dr H.K. Kohler, Director for Engineering and Design Courses, Department of Mechanical Engineering, University of Sheffield, Mappin Street, Sheffield S1 3JD, UK).

13-15 March, **First International Risk Seminar,** London (Ms D.E. Jarvis, PO Box 62, Beaconsfield, Bucks HP9 2NY, UK).

4-5 April, **Wind/Solar Energy Conference,** Kansas City (G.H. Stickney, College of Engineering, University of Missouri-Columbia, Columbia, MO 65211, USA).

5-8 April, **Electroanalysis in Biomedical, Environmental and Industrial Sciences,** Cardiff (Dr J.D.R. Thomas, Applied Chemistry Department, Redwood Building, UWIST, Cardiff CF1 3NU, UK).

9-11 April, **Interfacial Kinetics in Solution,** Hull (Professor D.H. Everett, Department of Physical Chemistry, School of Chemistry, Cantock's Close, Bristol BS8 1TS, UK).

11 April, **Opioids: Past, Present and Future,** Cambridge (Dr M.B. Tyers, Neuropharmacology Department, Glaxo Group Research Limited, Greenford Road, Greenford, Middlesex UB6 0HE, UK).

11-14 April, **International Conference on Combustion in Engineering,** Oxford (Institute of Mechanical Engineers, 1 Birdcage Walk, Westminster, London SW1H 9JJ, UK).

11-14 April, **7th UK Geographical Assembly,** Leicester (M.A. Khan, Department of Geology, University of Leicester, University Road, Leicester LE1 7RH, UK).

3 May, **International Symposium on Crop Protection,** Gent (The Secretary, Faculteit van de Landbouwwetenschappen, Coupure Links 533, B-9000 Gent, Belgium).

3-6 May, **Canadian Symposium on Remote Sensing,** Montreal (R. Desjardins, Department de Geographie, UQAM, BP 8888, Succ A, Montreal H3C 3P8, Canada).

5 May, **Energy Saving in the Chemical Industry,** London (Rubber and Plastics Research Association, Shawbury, Shrewsbury, Shropshire SY4 4NR, UK).

8-13 May, **Prevention of Occupational Accidents and Diseases,** Ottawa-Hull (The Xth World Congress on the Prevention of Occupational Accidents and Diseases, c/o Canadian Organising Committee, 500-300 Slater Street, Ottawa, Ontario, Canada K1P 6A6).

9-12 May, **International Conference and the Third Annual Meeting of the Electrophoresis Society,** Tokyo (Secretariat Electrophoresis '83, c/o Dr Nobuya Hashimoto, Department of Internal Medicine, The Jikei University School of Medicine, 3-25-8, Nisishimbashi, Minato-ku, Tokyo 105, Japan).

10-12 May, **Progress in Perinatal Medicine** Florence (P.G. Crosignani, IVth Department of Obstetrics and Gynaecology of the University of Milan, Via M. Melloni, 52-Milan, Italy).

10-21 May, **Course on Measurement, Analysis and Control of Noise,** Sheffield (Dr H.K. Kohler, Director for Engineering and Design Courses, Department of Mechanical Engineering, University of Sheffield, Mappin Street, Sheffield S1 3JD, UK).

16-20 May, **International Conference on Radioactive Waste Management,** Seattle (International Atomic Energy Agency, Wagramerstrasse 5, PO Box 100, A-1400 Vienna, Austria).

17-18 May, **Heat and Fluid Flow in Nuclear and Process Plant Safety,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London SW1H 9JJ, UK).

17-20 May, **Automated Manufacturing Exhibition and Conference,** Birmingham (Clapp and Poliak Europe Ltd, 232 Acton Lane, London W4 5DL, UK).

17-20 May, **Conference and Exhibition of Lasers and Electro-Optics (CLEO '83),** Baltimore (Publicity Chairman, CLEO '83, Tiemo von Zweck, Laser Power Optics, 11211 Sorrento Valley Road, San Diego, California, USA).

23-27 May, **International Conference on Graphite Intercalation Compounds,** Pont-a-Mousson, France (Dr Daniel Guerard, Laboratoire de Chimie Minerale Appliquee, Université de Nancy 1, BP 239, 54 506 Vandoeuvre les Nancy, France).

24-26 May **International Conference on Road Vehicle Handling,** Nuneaton (The Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London SW1H 9JJ, UK).

24-26 May, **International Conference on Ecology and Environmental Quality** Jerusalem (Professor H. Shuval, Chairman, Israel Ecological Society, Hebrew University-Hadassah Medical School, PO Box 1172, Jerusalem, Israel).

24-26 May, **Energy Storage,** Stratford Upon-Avon (Conference Organiser Energy Storage, BHRA Fluid Engineering Cranfield, Bedford MK43 0AJ, UK).

25 May, **The Ciba Foundation 34th Annua Lecture,** London (Miss J. Holman, The Ciba Foundation, 41 Portland Place London W1N 4BN, UK).

31 May-1 June, **Course on Water Supply and Sanitation for Developing Countries** Ottowa (Dr R. Droste, Water Sanitation Short Course, Department of Civi Engineering, University of Ottawa Ottawa, Ontario, Canada K1N 9B4).
